Vitamin B2 (riboflavin)	Anticholinergic drugs	Anticholinergic drugs inhibit intestinal absorption of riboflavin
	Tetracycline	Riboflavin reduces intestinal absorption and effectiveness of tetracyclines
	Doxorubicin	Riboflavin deactivates and is depleted by doxorubicin. (Is this what you mean?)
	Tricyclic antidepressants, phenothiazines	These compounds inhibit riboflavin's actions
	Phenytoin, methotrexate	
	Probenecid	Decreases the absorption of riboflavin from the gastrointestinal tract and decreases the urine riboflavin excretion
	Thiazide diuretics	Increase urine riboflavin excretion
Niacin/nicotinamide	Statins	Statins increase the risk of myopathy and rhabdomyolysis
Biotin	Antibiotics	Antibiotics reduce the intestinal microflora that produces biotin
	Anticonvulsants	Carbamazepine and phenytoin reduce biotin levels
Pantothenic acid (vitamin B5)	Tetracycline	Pantothenic acid interferes with intestinal absorption and effectiveness of tetracyclines
	Cholinesterase inhibitors	Pantothenic acid may increase the effects of cholinesterase inhibitors

CYP3A4, Cytochrome P450 3A4; NSAIDs, nonsteroidal antiinflammatory drugs.

## Vitamin A intake in chronic kidney disease patients

Data regarding vitamin A intake in patients with advanced CKD and dialysis patients are conflicting. No data are currently available concerning desirable vitamin A intake for nephrotic patients. Interestingly, regarding the incidence of CKD in a large cohort of healthy subjects with normal glomerular filtration rate (GFR), the upper quintiles of vitamin A intake were not associated with a significantly lower incidence of CKD during follow-up [14]; this is in opposition to the findings regarding the upper quintiles of folate and vitamins B12, C, and E. Vitamin A intake with the protein-restricted diets usually prescribed to nondialyzed CKD patients is reported in Table 26.3 from Stein et al. [15]. These investigators reported that the vitamin A intake with protein-restricted diets is slightly below the RDA. In 210 nondialyzed CKD patients (mean GFR,  $17.1 \pm 6.5$  mL/min), Chan et al. [16] reported an adequate vitamin A intake; however, the protein intake was large, 1.18-g protein/kg body weight/d. A more recent study addressed micronutrient intake in CKD, maintenance hemodialysis (MHD), chronic peritoneal dialysis (CPD) patients, and kidney transplant recipients who were not receiving vitamin supplements [4]. Vitamin A intake was found, respectively, to be 38%, 75%,

52%, and 55% of the EAR. Bossola et al. [3] obtained 3-day diet diaries in 128 MHD Italian patients and reported the vitamin A intake to be below the Italian RDI in 94.6% of the patients. In 242 continuous ambulatory peritoneal dialysis (CAPD) patients, Wang et al. [17] reported adequate vitamin A intakes, regardless of the adequacy of dialysis and of the residual renal function (RRF) of the patients. In contrast, Martin-Del-Campo et al. [18] reported vitamin A intake to be below the DRI in 40% of 73 CPD patients, independent of their nutritional status. Vitamin A intake was even lower in those patients [18] who had a serum C-reactive protein (CRP) greater than 12.2 mg/L. The lower vitamin A intake in this latter study was attributed to the specific characteristics of Mexican food. In summary, in many but not all studies of vitamin A intake in CKD 3–5D and kidney transplant patients, vitamin A intake was not uncommonly below the RDA.

## Vitamin A nutritional status in chronic kidney disease, chronic dialysis, acute kidney injury, and kidney transplant patients

Abnormally high plasma vitamin A levels and an increased rise in plasma vitamin A in response to a

TABLE 26.3 Typical vitamin contents of different diets prescribed to chronic renal failure patients<sup>a</sup>.

Dietary protein intake	Vitamin A (μg RE <sup>b</sup> )	Vitamin E (mg)	Vitamin K (μg)	Thiamine (mg)	Riboflavin (mg)	Biotin (μg)	Pyridoxine (mg)	Folic acid (μg)	Vitamin B12 (μg)	Niacin (mg)	Ascorbic acid (mg)	Pantothenic acid (mg)
40 g	556	16.0	80	1.2	0.8	13.4	1.4	50	0.6	9.0	107	3.0

RDA <sup>c</sup>	700–900	15	80–120	1.1–1.2	1.1–1.3	30 <sup>d</sup>	1.3–1.7 <sup>e</sup>	400	2.4	14–16	75–90 <sup>f</sup>	5 <sup>d</sup>

<sup>a</sup>Data calculated from food tables and referring to 24-h intake of the nutrient from the diet.<sup>b</sup>RE: Retinol equivalents.<sup>c</sup>RDA: Recommended dietary allowance for healthy, nonpregnant, nonlactating adults.<sup>d</sup>This value is not an RDA; there is inadequate scientific evidence to allow the calculation of RDA. Recommended intake, termed “adequate intake” is used instead. It is derived from experimental data or by an approximation of observed mean intakes, as suggested by the Standing Committee on the Scientific Evaluation of Dietary Reference Intakes [348].<sup>e</sup>In female and male adults below the age of 50, the RDA is 1.3 mg/d. Over the age of 50 the RDA is respectively 1.5 and 1.7 mg/d for women and men.<sup>f</sup>Values of the RDA are for nonsmoking female and male adults. Add 35 mg/d for smokers [48].From Stein G, Spersneider H, Koppe S. Vitamin levels in chronic renal failure and need for supplementation. *Blood Purif* 1985;3:52–62.

vitamin A load were reported in CKD patients as long ago as 1945 [19]. Investigators have consistently found elevated plasma concentrations of total vitamin A, RBP-bound vitamin A, and free vitamin A in nondialyzed CKD patients and maintenance dialysis patients, including children [15,20–25]. In patients with the nephrotic syndrome, plasma RBP, retinol, and retinyl esters levels have also reported to be increased [26], even in the absence of renal failure. Recently, Bataille et al. [27] found that 91.9% of 123 MHD patients had high plasma retinol concentrations. Increased plasma vitamin A in CKD is classically attributed to altered RBP and RBP–retinol metabolism. After the delivery of retinol to target tissues, free RBP can be filtered by the glomerulus and catabolized by renal tubule cells. Thus in renal failure, RBP catabolism is impaired, resulting in increased plasma RBP and plasma RBP/prealbumin and RBP/retinol ratios [28]. Also, the small proportion (5%) of the RBP–retinol complex that is not bound to transthyretin is filtered at the glomerulus. This complex is captured by the proximal tubular cells by a specific apical receptor, megalin, which allows for retinol recycling into the blood stream at the basolateral level of the cell. Knockout mice for megalin display a urinary loss of the RBP–retinol complex [29]. Thus the loss of GFR in kidney failure contributes to the elevated vitamin A plasma levels. However, the renal clearance of RBP-4 has recently been found to be independent of the GFR in patients with various stages of CKD (Fig. 26.1) [30], and these investigators hypothesize that the increase in plasma retinol and RBP-4 may be more of hepatic origin than related to decreased removal of RBP-4 by the kidney.

As shown many years ago, hemodialysis (HD) treatment does not change vitamin A levels [21]; indeed, substantial losses of vitamin A into dialysate would not be expected because of the relatively large size of the vitamin A–RBP–prealbumin complex. However, serum  $\beta$ -carotene, ubiquinol, and lycopene have been found to be lower in MHD patients than in controls

FIGURE 26.1 The absence of relationship between eGFR and renal clearance of retinol-binding protein-4. eGFR, Estimated glomerular filtration rate. Source: By Jing J, Isoherranen N, Robinson-Cohen C, Petrie I, Kestenbaum BR, Yeung CK. Chronic kidney disease alters vitamin A homeostasis via effects on hepatic RBP4 protein expression and metabolic enzymes. *Clin Transl Sci* 2016;9:207–15, with permission.

[23,31], and serum  $\beta$ -carotene and ubiquinol fall further after a single HD session. There are no published data on the dialysis kinetics of vitamin A and RBP handling in MHD patients treated with convective techniques and daily dialysis. Data are conflicting as to whether vitamin A and RBP are present in the effluent peritoneal dialysate [22,32].

In patients with AKI, serum vitamin A levels were found to be normal in one study [28], decreased in another study (with normal serum RBP levels) [33], and increased in a third study of AKI patients receiving total parenteral nutrition (TPN) containing standard retinol supplementation [34]. In 40 patients treated with continuous veno-venous HD (CVVHD), Datzmann et al. [35] did not detect vitamin A in the spent dialysate. Plasma vitamin A levels decrease slowly toward normal after renal transplantation. Yatzidis and coworkers reported that more than 20 months may elapse in patients with a well-functioning kidney transplant before plasma vitamin A levels are normal [36].

## Clinical effects of altered vitamin A nutrition

### Potential risk of vitamin A toxicity

Whether there is an increased risk of vitamin A toxicity in nondialyzed CKD patients and chronic dialysis patients is controversial [37]. Many CKD patients who have increased plasma vitamin A levels (up to three to four times normal) do not show evidence for toxicity [38,39]. Elevated plasma vitamin A in CKD is considered by many authors to be relative, due to the protective effects of increased plasma RBP, and to have no clinical significance, if the vitamin A/RBP ratio is normal or low. Vitamin A toxicity is believed to occur when plasma retinyl esters in the lipoprotein fractions increase [11,28]. Whether vitamin A accumulates in solid tissues in CKD patients is also controversial [20,39–41]. Therefore it is not known whether the increased plasma vitamin A levels that are commonly found in CKD and chronic dialysis patients are hazardous. In patients without CKD who have vitamin A overload and toxicity, large amounts of vitamin A may accumulate in the liver. The clinical signs of vitamin A intoxication, cutaneous lesions (fissures, dryness, desquamation, and yellowish appearance), headaches and central nervous system manifestations, joint pains, bone tenderness to palpation, anemia, hepatomegaly, and muscle stiffness [11], are not specific indicators for vitamin A toxicity. Hence, these signs, when present, are not necessarily due to vitamin A toxicity.

### Vitamin A and hypercalcemia

Intriguingly, in CKD patients who did not have other evidence for vitamin A toxicity, a correlation between plasma vitamin A concentrations and serum calcium levels has been reported [42]. The bone reabsorptive effects of excess vitamin A have been known for many years, and there is a report of hypercalcemia with elevated serum vitamin A levels in CKD patients as long ago as 1971 [43]. MHD patients who were taking modest doses of vitamin A supplements, 2500–15,000 IU/d, had higher serum vitamin A and calcium concentrations than those who were not. The association between elevated plasma retinol and hypercalcemia has also been found in children with CKD as early as stage 2 as well as in children undergoing dialysis therapy [44]. However, such correlations between elevated plasma vitamin A and increased serum calcium or serum alkaline phosphatase have not been consistently found. The mechanism of hypercalcemia with vitamin A toxicity is related to the osteolytic action of the retinoids on bone. Vitamin A toxicity should be considered in the differential diagnosis of hypercalcemia in CKD patients.

### Vitamin A and outcomes

The prognostic value of plasma vitamin A levels in MHD and renal transplant patients has been previously analyzed. In a post hoc analysis of the 4D study in which the participants in the study were prevalent diabetic MHD patients, Espe et al. [45] found that the participants who were in the lower quartiles of plasma retinol (Fig. 26.2) and RBP-4 concentrations displayed an increased risk of sudden death, infection-related death, and overall mortality. Interestingly, the lower quartile of plasma retinol in these patients remained above the normal range of plasma retinol. These results confirm previous data reported in a smaller cohort of MHD patients [46]. One possible interpretation is that the lower plasma retinol levels are an indirect marker of inflammation. This is consistent with data from CPD patients by Martin-Del-Campo et al., mentioned earlier [18], who found a significantly lower vitamin A intake in the patients whose serum CRPs were in the highest quartile. Another hypothesis is that retinol behaves as a nutritional surrogate since its metabolism is closely associated with that of transthyretin. Bataille et al. [27] confirmed a higher mortality in MHD patients who were in the lowest plasma retinol quartile, but the significance disappeared when transthyretin was introduced in the statistical model. Also, in renal transplant recipients, as in MHD patients, decreased survival has been observed in patients in the lower tertile for plasma retinol [47]. In contrast, in the same study, plasma vitamin E and a variety of carotenoids, including  $\beta$ -carotene, were not associated with patient survival.

FIGURE 26.2 Relationship between plasma vitamin A plasma levels and sudden cardiac death in maintenance hemodialysis patients. ## Vitamin A supplementation in chronic kidney disease, chronic dialysis, and transplant patients

Plasma vitamin A levels in advanced CKD and chronic dialysis patients (CKD 3–5D) are elevated, and vitamin A deficiency has rarely been observed. However, even relatively small supplements of vitamin A (i.e., 2500–15,000 IU, 750–4500 µg of REs) may cause vitamin A toxicity. There is a consensus that vitamin A supplements in doses larger than the recommended daily allowance (RDA) for normal healthy adults (i.e., 700–900 µg of RE, or 2300–3000 IU [48]) should not be given to normal adults, and the same recommendation is made for CKD, MHD, CPD, and kidney transplant patients. The recommendations in the KDOQI CPGs for nutrition in CKD are consistent with the RDA [1]. However, findings from three studies demonstrate that, among MHD patients, those individuals with the lowest plasma retinol levels (but which, on average, were still above normal concentrations) have increased mortality [27,45,46]. Patients with nephrotic range proteinuria excrete substantial amounts of vitamins that are bound to protein. Hence, a daily intake of the RDA for vitamin A is recommended for nephrotic individuals. For renal transplant recipients, vitamin A supplements do not appear necessary unless their vitamin A intake is low. Vitamin A supplements are probably not necessary for AKI patients unless they are nourished by TPN for at least 2 weeks. Given the risks of vitamin A toxicity in advanced CKD patients and reports of vitamin A toxicity in TPN patients with AKI receiving as little as 1500 µg of RE (5000 IU)/d [34], it is recommended that no more than the RDA for vitamin A (700–900 µg/d or 2300–3000 IU/d—for nonpregnant, nonlactating adults) should be given for AKI patients receiving TPN as their sole nutritional source (Table 26.4).

### Summary:

- Serum vitamin A is frequently increased in advanced CKD, MHD, and CPD patients, even though vitamin A intake is usually decreased.
- The mechanism for this increase has been attributed to decreased catabolism of RBP-4, but recent data suggest that enhanced hepatic synthesis may contribute to this elevation.
- There is no obvious toxicity that has been associated with the typical increase in plasma vitamin A levels found in advanced CKD and chronic dialysis patients.
- However, hypercalcemia may be associated with high plasma retinol levels.

Continued

- The lower quintiles of plasma retinol levels, even if still above normal values, are associated with increased mortality in MHD patients and renal transplant recipients. Inflammation and poor nutritional status may have a causal role in this relationship.
- There is no evidence suggesting that vitamin A should be routinely supplemented for advanced CKD, chronic dialysis, or kidney transplant patients. This position is consistent with the KDOQI CPGs on nutrition in CKD.

## Vitamin E, physiology, biochemistry, and nutritional status in chronic kidney disease patients

### Vitamin E physiology and biochemistry

Vitamin E is a fat-soluble vitamin for which the main active compound is  $\alpha$ -tocopherol (Table 26.1); there are other naturally occurring isomers of vitamin E ( $\beta$ ,  $\gamma$ ,  $\delta$ ) as well. A genetic deficit of the  $\alpha$ -tocopherol transfer protein provokes a severe neurologic disorder that occurs between the ages of 5 and 15 years and is called AVED (ataxia with vitamin E deficiency), also referred to as Friedreich-like ataxia. It is associated with a markedly reduced serum  $\alpha$ -tocopherol level. Only supplementation with  $\alpha$ -tocopherol can improve the clinical burden of this disease; the other isoforms of tocopherol are ineffective. Based on this fact, Azzi recently disputed the appellation of “vitamin” for the other isoforms of tocopherol [49].

The main sources of vitamin E are vegetable oils, such as corn, soybean, wheat germ, and sunflower oil [50]. Animal products are not rich sources of vitamin E. Vitamin E metabolism has recently been extensively reviewed [51]. After intestinal absorption of vitamin E congeners, these compounds are transported with fat, mainly through the lymphatic flow, into the venous circulation [52]. In plasma, there is no specific carrier for  $\alpha$ -tocopherol. It is transported in plasma by lipoproteins, and its plasma concentration is affected by the lipid content of blood. Assessment of the nutritional status of vitamin E is difficult. HPLC has been widely used for decades to measure serum vitamin E levels [53,54]. The cell membrane concentrations of  $\alpha$ -tocopherol and/or its antioxidant activity may give more helpful information concerning the adequacy and activity of tissue  $\alpha$ -tocopherol levels than plasma  $\alpha$ -tocopherol concentrations. Vitamin E is the main antioxidant in biological membranes and protects phospholipid membranes from oxidative stress. Vitamin E deficiency due to intestinal malabsorption has been reported to increase hemolysis by causing membrane fragility [53]. Vitamin E also has antiinflammatory properties, including, among others, regulation of protein kinase C, PPAR- $\gamma$ , and NF- $\kappa$ B, that has antiatherogenic

activities [55]. Several medications may interfere with vitamin E metabolism or actions. These are summarized in Table 26.2.

Epidemiological studies indicate a reduced risk of coronary heart disease in men and women who have higher intakes of vitamin E from foods [56,57]. The mechanism for this protective effect is attributed to decreased oxidation of LDL cholesterol, a key step in the pathogenesis of the fatty streak, the first step in the development of the atheromatous plaque. On the other hand, vitamin E may promote synthesis and secretion of selectin, an adhesion molecule involved in the endothelial attachment of monocytes to endothelial cells, another step in atherogenesis [58]. However, as with vitamin A, large-scale clinical trials have failed to demonstrate a benefit of vitamin E for the prevention of cancer or CV disease [13].

### Vitamin E intake in chronic kidney disease patients

In a large cohort of healthy subjects without CKD, people who were in the upper quintiles for dietary intake of folates, vitamins B12, C, and E, as well as magnesium and potassium, displayed a significantly lower incidence of CKD during follow-up. This is in opposition to the higher incidence of CKD in people who are in the higher quintile for sodium intake [14]. Different amounts of vitamins A, B2, B3, B6, and phosphate, calcium, selenium, and zinc had no association with the incidence of CKD. Vitamin E intake is slightly decreased in CKD patients ingesting protein-restricted diets (Table 26.3). In 210 nondialyzed CKD patients, Chan et al. [16] identified an insufficient vitamin E intake in 61.8% of the patients. Jankowska et al. [4] found vitamin E intake to be below the EAR in 58%–75% of CKD, MHD, CPD, and kidney transplant patients. Bossola et al. [3] confirmed from 3-day diet diaries in 128 MHD Italian patients that 66.7% of the patients had vitamin E intakes below the RDI.

### Vitamin E nutritional status in chronic kidney disease 1–5D, kidney transplant, and acute kidney injury patients

In nondialyzed patients with advanced CKD, plasma vitamin E levels are usually within the normal range [59]. Malnutrition may influence vitamin E status; lower serum  $\alpha$ -tocopherol levels are found in malnourished CKD patients compared to well-nourished individuals [60]. Peuchant et al. [61] found decreased  $\alpha$ -tocopherol in red blood cells (RBCs) from nondialyzed CKD patients who had increased erythrocyte peroxidation, as indicated by elevated intraerythrocyte malondialdehyde (MDA) concentrations. In MHD patients, no difference in plasma vitamin E concentrations are found between pre- and postdialysis samples [31]. Serum  $\alpha$ -tocopherol

levels in MHD patients are reported to be low [31], normal [59], or increased [15,27]. Bataille et al. [27] found, in nonselected MHD patients, high levels of serum tocopherol in 72.4% of the patients, whereas only 2.4% had low levels. In CPD patients, data regarding vitamin E status are also conflictory. In 40 kidney transplant patients, McGrath et al. [62] found vitamin E to be normal both in 20 patients who were receiving cyclosporine and in 20 patients receiving azathioprine (AZA) and glucocorticoids. In critically ill patients with AKI, plasma vitamin E levels are decreased whether or not they are treated with continuous hemofiltration [63]. Vitamin E was not detectable in the spent dialysate in AKI patients treated with CVVHD.

### ***Vitamin E, oxidant stress, and contrast-induced nephropathy in chronic kidney disease***

Much evidence indicates that nondialyzed advanced CKD patients and MHD and CPD patients suffer from oxidant stress, and this condition is associated with adverse CV complications [64] [see Chapter 8: Catalytic (Labile) Iron in Kidney Disease]. Many studies have examined the effects of oral vitamin E supplementation on oxidant stress, and this has been extensively analyzed by Coombes and Fassett [65]. Most studies using  $\alpha$ -tocopherol showed that it reduces markers of oxidant stress. The SPACE study was a randomized controlled trial of 196 MHD patients that found oral vitamin E, 800 IU/d, was of beneficial effect in the secondary prevention of CV events [66]. However, the HOPE study did not show clinical benefits of vitamin E supplements in individuals with or without chronic renal insufficiency [67,68]. Moreover, subsequent analysis of the HOPE trial and its extension (HOPE-TOO) indicated an increased risk of heart failure in patients receiving long-term vitamin E supplements [69]. Other trials involving small numbers of MHD and/or CAPD patients have shown that  $\alpha$ -tocopherol therapy has a number of potentially beneficial effects, including vitamin E enrichment of LDL [70], improved endothelial function in diabetic MHD patients [71], increased erythrocyte life span or reduced doses of erythropoietin-stimulating agents (ESA) [72,73], and decreased LDL susceptibility to oxidation [74]. In renal transplant patients, oxidative damage is particularly likely to occur at several steps during the actual transplantation process. Reperfusion after cold ischemia may lead to marked oxidative bursts in the kidney. An antioxidant mixture that included 10 mg of  $\alpha$ -tocopherol, given 30 minutes before reperfusion, was able to reduce the degree of lipid peroxidation as assessed by the plasma MDA levels [75]. Cristol et al. [76] found evidence for increased oxidative stress in 77 long-standing kidney transplant recipients, including individuals with and without chronic rejection. Oxidative stress appeared to be greater in the patients with chronic rejection. Patients

treated with tacrolimus were found to have increased susceptibility to oxidation when compared to cyclosporine-treated patients [77]. However, McGrath et al. [62] did not observe differences in plasma TBARS (thiobarbituric acid reactive substances) and plasma vitamin E concentrations in patients receiving cyclosporine or AZA when compared to controls. There does not appear to be enough evidence yet to recommend the routine administration of  $\alpha$ -tocopherol to renal transplant recipients [78].

Recently, vitamin E has been evaluated with regard to preventing contrast-induced nephropathy (CIN). Rezaei et al. [79] conducted a double-blind, placebo-controlled trial in 300 patients with estimated GFR (eGFR) < 60 mL/min/1.73 m<sup>2</sup> and undergoing coronary angiography. Patients were randomized to receive a saline infusion or a saline infusion plus 1000 mg of vitamin E. The incidence of CIN was significantly reduced in the vitamin E group (6.7% vs 14.1%) with an odds ratio by multivariate analysis of 0.41 [79]. In a metaanalysis, including 19 trials, the relative risk of CIN was reduced to 0.39 (95% CI 0.24–0.62,  $P < .0001$ ) by adding vitamin E versus saline [80].

### ***Vitamin E–coated hemodialysis membranes***

Whether vitamin E–coated membranes will reduce oxidative stress during HD treatment has been investigated. Most clinical trials with these membranes were carried out for at least 3 months; the membranes appear to increase plasma or RBC vitamin E levels [81] and decrease plasma MDA [82]. Other observed potentially beneficial effects of vitamin E–coated membranes include decreased neutrophil activation, reduced prooxidant leukocyte activity, decreased intradialytic IL-6 production, lower serum oxidized-LDL and ADMA (asymmetrical dimethylarginine), and reduced oxidative damage to DNA. In a 6-month controlled trial, the use of vitamin E–coated dialyzer membranes decreased serum CRP and oxidized-LDL levels [83]. Regarding the response to ESA, the results are conflicting. Comparing MHD patients treated with vitamin E–coated polysulfone membrane versus those treated with standard polysulfone for 1 year, Sanaka et al. [84] found no effect of vitamin E, whereas a more recent trial [85] described a decrease in the erythropoietin (EPO) resistance index with vitamin E. No trial has yet examined the effect of these vitamin E–coated membranes on morbidity or mortality.

### ***Vitamin E and cramps in maintenance hemodialysis patients***

Vitamin E alone, or combined with vitamin C, is reported to reduce the incidence of muscle cramps in MHD patients [86].

### **Vitamin E supplementation in chronic kidney disease, chronic dialysis, and kidney transplant patients**

The SPACE study [66] and the well-recognized prooxidant state of uremia would support the use of  $\alpha$ -tocopherol supplements in chronic dialysis patients to prevent CV events. However, the HOPE study did not show clinical benefits of supplemental vitamin E, 400 IU/d, supplements in individuals with or without chronic renal insufficiency [67,68]. Moreover, subsequent analyses of the HOPE trial and its extension (HOPE-TOO) have shown an increased risk of heart failure in patients receiving this vitamin E supplement [69]. People without kidney disease who were given pharmacological doses of vitamin E have displayed platelet dysfunction and interference with the vitamin K–dependent coagulation factors [87]. Miller et al. [88], in a meta-analysis, including 19 trials with 135,967 patients, not specifically with CKD, found increased mortality with high doses of vitamin E therapy ( $\geq 400$  IU/d). Since the benefits of vitamin E reported in the SPACE trial have not been confirmed and because of the risks of increased morbidity and mortality with high vitamin E doses, it would appear prudent to wait for more data before recommending supplemental daily vitamin E for CKD 3–5D and transplant patients. This recommendation is consistent with the KDOQI nutrition in CKD update [1] (Table 26.4).

#### **Summary:**

- Reports on the vitamin E status of CKD patients are conflicting.
- A majority of nondialyzed, advanced CKD, MHD, and CPD patients have low vitamin E intakes.
- Critically ill patients with AKI often have low serum levels of vitamin E.
- The SPACE study, which showed a lower incidence of CV events in MHD patients receiving vitamin E therapy, has not been confirmed.
- The HOPE-TOO analysis has raised questions concerning the long-term safety of vitamin E supplements.
- There are no studies concerning the effects of vitamin E–coated hemodialysis membranes on morbidity or mortality in MHD patients.
- Vitamin E appears to be effective for preventing CIN.
- No routine supplementation of vitamin E is indicated in CKD, dialysis, and transplant patients because of the paucity of clinical benefits reported and potential vitamin E toxicity.

## Vitamin K, physiology, biochemistry, and nutritional status in chronic kidney disease patients

### Vitamin K physiology and biochemistry

Vitamin K metabolism has been extensively reviewed [89–92]. Two classes of compounds, phyloquinone (K1) and menaquinones (K2), are primarily responsible for vitamin K activity. Phyloquinone (Table 26.1) is primarily found in green and leafy vegetables (e.g., spinach, kale, cabbage, and broccoli). Menaquinones are of bacterial origin and are found in fermented food, meat, and dairy products and represent 25% of the total vitamin K intake. The intestinal absorption of these compounds requires biliary and pancreatic juices and occurs in the small bowel where vitamin K is incorporated into chylomicrons. The importance of intestinal bacterial synthesis of vitamin K (menaquinone) as a vitamin source is still controversial. Its importance had been emphasized because of the frequency of vitamin K deficiency associated with the use of large-spectrum antibiotics. However, antibiotic therapy is not necessary for the development of vitamin K deficiency. Moreover, certain antibiotics may promote vitamin K deficiency by an independent mechanism. Antibiotics that have an *N*-methyl-5-thiotetrazole side chain, like cefamandole and cefoperazone, have a warfarin-like effect and interfere directly with the gamma-carboxylation of proteins, independently of any suppression of intestinal flora [87]. Furthermore, a vitamin K1 deficient state is easily induced experimentally by restricting food for a few days or weeks. This leads to decreased levels of plasma descarboxy-prothrombin (currently referred to as PIVKA-2, see later) and reduced urinary excretion of gamma-carboxyglutamic acid [93]. Finally and more specifically, the effect of phosphate binders on vitamin K intestinal absorption have been recently reviewed [94]. Menaquinone absorption is impaired by calcium-based and lanthanum binders. Sevelamer hydrochloride and sevelamer carbonate impair absorption of liposoluble vitamins, including vitamin K. No data are currently available regarding the vitamin K effects of iron-based phosphate binders. Other medications, beside sevelamer and vitamin K antagonists (VKAs), may interfere with vitamin K metabolism. They are summarized in Table 26.2.

The uptake of vitamin K by the liver depends on  $\beta$ -lipoproteins and the clearance of the plasma chylomicron remnants, including its apo-E component. There is no specific carrier for vitamin K in plasma. Plasma phyloquinone levels are found to be lower in elderly individuals as compared to young subjects [95]. Vitamin K turnover is rapid, and the body pool is small (Table 26.1). The kidney has no major role in vitamin K metabolism [91].

Vitamin K is a coenzyme for the posttranslational carboxylation of glutamate residues in several proteins, which results in gamma-carboxyglutamate (Gla) residues on these latter proteins. These latter proteins are called Gla-proteins, and they may be highly functional (see next). The Gla-residue in protein binds to calcium. In the process of forming the Gla-residue, vitamin K is transformed from the hydroquinone form (KH<sub>2</sub>) to the epoxide form (KO), releasing during this process the amount of energy required to generate the carboxylation reaction. The epoxide form of vitamin K is then recycled back to the hydroquinone form; thus a rather small quantity of vitamin K can generate a much larger amount of the Gla proteins. Indeed, the urinary excretion of Gla residues is 200–500 times greater than the dietary intake of vitamin K. The currently known Gla-proteins are found in the coagulation cascade, in bone and dentin, in microsomes of tubular cells [96], and in atherogenic plaques. The importance of vitamin K for the normal coagulation cascade is well known. In fact, the name “vitamin K” reflects this association (K for koagulation). The procoagulant factors that contain Gla residues, and hence require vitamin K for their posttranslational carboxylation, are prothrombin (Factor II), proconvertin (Factor VII), Christmas factor (Factor IX), and Stuart factor (Factor X). The anticoagulation effect of coumarin derivatives is related to the blockade of the dithiol-dependent reductases that are necessary for the recycling of vitamin K. However, the production of several inhibitors of coagulation is also vitamin K dependent, including proteins C, S, and Z. This is the explanation for the uncommon and paradoxical thrombotic complications of coumarin therapy, such as skin necrosis [97].

Two Gla-proteins, osteocalcin and matrix Gla protein (MGP), are also present in bone. Osteocalcin is the most abundant noncollagenous protein of bone and is a specific marker for osteoblast activity. In vitro, osteocalcin binds to hydroxyapatite and inhibits its formation. This action requires the vitamin K-dependent carboxylation of the protein. MGP regulates calcium deposition in the tissues. MGP knockout mice present with extensive lethal vascular calcifications [98]. The carboxylated proteins in bone play a key role in bone homeostasis. Women with hip fractures have been found to have lower plasma vitamin K levels [99], and the Hordaland Health Study has shown that hip fracture is associated with a low vitamin K1 intake [100]. It has been suggested that patients receiving warfarin therapy have greater bone density loss, but this remains controversial [101,102]. Whereas the phyloquinone (vitamin K1) is mainly retained in the liver where it carboxylates the proteins of the coagulation cascade, menaquinone

derivatives (vitamin K<sub>2</sub>) have longer half-lives and are distributed in extrahepatic tissues, such as bone and vessels [91].

Assessment of vitamin K status is complex and has been recently reviewed [103,104]. For direct assessment of plasma vitamin K, the reference method is HPLC. Accuracy of this method is complicated by important interference from lipids and the need for improved electrochemical detection to enhance sensitivity and specificity. Combined HPLC and mass spectrometry (tandem technique) have provided high sensitivity and specificity results, especially for menaquinone, the assessment of which is hampered by triglyceride interference when classical methods are used. Several functional markers are more effective for detecting vitamin K functional deficiency. Prothrombin time is not a reliable test to assess vitamin K status. PIVKA-2 (des-gamma-carboxy prothrombin induced by vitamin K absence-Factor II) reflects hepatic vitamin K functionality. It decreases with vitamin K supplementation and increases with VKAs. Dephosphorylated-uncarboxylated MGP (dp-ucMGP), dephosphorylated-carboxylated MGP (dp-cMGP), uncarboxylated osteocalcin, and Gas-6 (inhibitor of vascular smooth cells calcifications) reflect extrahepatic vitamin K functionality. Regarding osteocalcin, its specificity for vitamin K function is disputed, especially in dialysis patients, because plasma osteocalcin levels are influenced by vitamin D and parathyroid hormone (PTH), which are both frequently altered in CKD. dp-ucMGP is a good indicator of vitamin K functionality, but it is not easy to measure dp-ucMGP in a typical clinical laboratory.

### Vitamin K intake in chronic kidney disease patients

Data regarding vitamin K intake in nondialyzed advanced CKD patients and chronic dialysis patients are scarce. In several studies concerning intake of various vitamins in these patients, their vitamin K intake was not addressed (see later). Protein-restricted diets are most likely to contain low quantities of several vitamins, including vitamin K (Table 26.3). Cranenburg et al. [105] reported on 4-day food records from 40 MHD patients who had low intakes of vitamins K<sub>1</sub> and K<sub>2</sub>. The intake was lower on dialysis days and during the weekend. Prescribed diets for MHD patients, which commonly are restricted in leafy vegetables to prevent potassium load and in cheese to restrict phosphate intake, were proposed as an explanation for the low vitamin K intake. Low vitamin K intake in chronic dialysis patients has been confirmed by Fusaro et al. [106] who compared the vitamin K<sub>1</sub> intake from 7-day food questionnaires in 91 MHD patients. They found that 71.5%–89.2% of the patients had a vitamin K<sub>1</sub> intake below the Italian recommendations.

### Vitamin K nutritional status in nondialyzed chronic kidney disease, chronic dialysis, and kidney transplant patients

There has been growing interest regarding vitamin K in both CKD and chronic dialysis patients because vascular calcification in CKD patients is highly prevalent and because the use of medicines that are VKAs is strongly associated with calciphylaxis, a life-threatening condition that occurs mainly in MHD patients. In the past, few studies systematically examined the vitamin K status of CKD and chronic dialysis patients, and the results were conflicting. Plasma vitamin K levels were found to be normal by Malyszko et al. [107] in advanced CKD, MHD, CPD, and kidney transplant patients. Robert et al. [108] reported a high plasma level of phylloquinone in MHD patients. In contrast, low plasma phylloquinone levels were described in some advanced CKD (6%), MHD (29%), and CPD (24%) patients [109–111]. However, the plasma phylloquinone level itself is not a sensitive indicator of subclinical vitamin K deficiency. In 172 nondialyzed CKD 3–5D patients [112], the plasma phylloquinone level was found to be normal in 94% of the patients; but 60% of the patients had serum uncarboxylated osteocalcin >20% (a deficiency threshold), which is a marker of vitamin K deficiency associated with both advanced CKD and high serum CRP levels. Also 97% of the patients had subclinically deficient liver vitamin K levels as assessed from the serum level of PIVKA-2. This latter marker was significantly associated with serum triglycerides and the apo-E4 allele and was inversely correlated with vitamin K intake. In another cohort of 107 CKD 3–5 and dialysis patients, serum dp-ucMGP increased with the stage of CKD and was positively and independently related to vascular calcifications and patient survival [110,113]. In 50 MHD patients, Aoun et al. [114] found that 98% had vitamin K deficiency based on plasma dp-ucMGP. In 188 MHD patients compared to 88 healthy controls, Schlieper et al. [115] confirmed that vitamin K deficiency was common in chronic dialysis patients. They found increased PIVKA-II in 64% of the patients; plasma dp-cMGP and dp-ucMGP levels were, respectively, 3.3- and 6.5-fold greater than in controls. In 28 CPD patients, Stankowiak-Kulpa et al. [116] reported increased plasma PIVKA-II levels indicating vitamin K deficiency, whereas prothrombin time and INR were normal. In 518 kidney transplant patients [117], serum dp-ucMGP was reported to be above the normal range in 91% of the patients indicating vitamin K deficiency. However, Jansz et al. [118] reported lower serum uc-dpMGP levels reflecting better vitamin K status in kidney transplant recipients compared to chronic dialysis patients. In addition to an improvement in GFR and food intake in renal transplant patients, the withdrawal of sevelamer therapy was considered to be an important

factor associated with improvement in vitamin K status, because serum uc-dpMGP decreased significantly after sevelamer monotherapy was discontinued. Thus phosphate binders may predispose to vitamin K deficiency in chronic dialysis patients, as previously mentioned.

## Clinical effects of vitamin K deficiency in chronic kidney disease

### Glomerular filtration rate decline

In people without CKD, Wei et al. [119] reported that high serum levels of dp-ucMGP were a risk factor for GFR decline.

### Bone status in chronic kidney disease patients

The effect of vitamin K supplementation on bone health in the general population is controversial [120]. Apalset et al. [100] in the Hordaland study in Norway (the male and female subjects were between 71 and 75 years of age) reported that people in the lower quartile of vitamin K1 intake were at a 57% increased risk of hip fracture, whereas the quartile of vitamin K2 intake or the presence of the apo-E4 genotype was not associated with increased risk. Caluwe et al. [103] reviewed 17 trials regarding the effects of vitamin K supplements on bone mineral density in non-CKD patients. The results were contradictory. The authors commented that some of the trials were lacking

power, and that low compliance might have diminished the benefits of vitamin K supplementation.

Two decades ago, in MHD patients an inverse relationship was reported between a history of bone fractures and the plasma phyloquinone levels or the proportion of carboxylated versus noncarboxylated osteocalcin in plasma [121]. Serum PTH levels were high ( $> 300$  ng/L) only in patients with low plasma phyloquinone concentrations. These latter patients also had an abnormally high incidence of the apo-E3/4 and E4/4 genotype which may indicate impaired tissue uptake of phyloquinone from chylomicrons [122]. MHD patients with adynamic bone disease who received vitamin K supplements for 1 year displayed both a significant increase in serum PTH, alkaline phosphatase, and the cross-linked N-terminal telopeptide of type I collagen and a trend toward decreased serum osteoprotegerin, a well-recognized factor associated with vascular calcification [123]. More recently, Fusaro et al. [124] compared the prevalence of vertebral fractures and osteocalcin in MHD patients with or without prescription of VKAs. Male patients prescribed VKAs had a significantly higher frequency of vertebral fractures and lower plasma osteocalcin levels.

### Vascular calcifications, calciphylaxis, and outcomes

Aoun et al. [114] reported a linear relationship between the plasma dp-ucMGP and the aortic calcification (AC-24) score (Fig. 26.3). The frequently altered

**FIGURE 26.3** Relationship between plasma dp-ucMGP concentrations and aortic calcification severity score ( $r = 0.43$ ;  $P = .002$ ). dp-ucMGP, Dephosphorylated-uncarboxylated matrix Gla protein. Source: Reproduced from Aoun M, Makki M, Azar H, Matta H, Chelala DN. High dephosphorylated-uncarboxylated MGP in hemodialysis patients: risk factors and response to vitamin K2, a pre-post intervention clinical trial. *BMC Nephrol* 2017;18:191. Reproduced with permission from the Editor.

status of vitamin K in advanced CKD patients and its association with vascular calcification and outcomes were recently reviewed [103]. Most, but not all, of the studies reported a positive relationship between ucMGP and vascular calcification and/or overall mortality in CKD, in chronic dialysis, and kidney transplant patients [103]. In 350 CKD patients (nondialyzed and chronic dialysis patients), plasma dp-ucMGP was positively associated with a high vascular calcification score and/or vascular stiffness. Also, all-cause mortality was associated with increased plasma dp-ucMGP in 706 MHD and kidney transplant patients. Delanaye et al. [125] found in 160 MHD patients a significant, positive relationship between plasma dp-ucMGP and the calcification score (Kauppila method). It is noteworthy that the plasma dp-ucMGP levels were dependent on whether patients were receiving VKA therapy. Also, in 518 kidney transplant recipients [117], plasma dp-ucMGP was above the normal range in 91% of the patients, indicating vitamin K deficiency. During an average follow-up of 9.8 years, patients in the highest quartile of plasma dp-ucMGP concentrations had a significantly higher risk of mortality (HR: 3.10; 95% CI, 1.87–5.12;  $P < .001$ ). Moreover, an altered ratio in plasma of carboxylated:uncarboxylated MGP was strongly associated with calciphylaxis in 20 MHD patients as compared to 20 matched patients who did not have this altered ratio [126]. VKAs are a recognized risk factor for calciphylaxis [127]. The association of prescribed VKA and increased ucMGP with arterial calcifications has been reported in young subjects without CKD [128]. In 387 MHD patients, warfarin was significantly associated with aortic and iliac calcifications in a multivariate analysis (odds ratio  $>2$  for both the aorta and the iliac) [129]. Notwithstanding the increased risk of plasma uc/cMGP imbalances with VKA treatment, other analyses of potential benefits versus risks associated with VKA treatment have given conflicting results [130,131].

### Vitamin K supplementation in chronic kidney disease, chronic dialysis, and kidney transplant patients

Because of the high risk of thrombosis associated with the nephrotic syndrome and the frequent need for coumarin derivatives for its prevention, vitamin K supplements are not routinely recommended for nephrotic patients. Since CKD 3–5D patients are usually not considered to have vitamin K deficiency, as determined by the more commonly performed measures of altered clotting factors or clotting function, vitamin K supplements generally have not been recommended (Table 26.4). Traditionally, vitamin K supplements

have been proposed for patients who are eating poorly and receiving antibiotics that may suppress intestinal bacteria that synthesize vitamin K; these patients tend to be considered at increased risk for developing vitamin K deficiency, particularly when these latter conditions persist for extended periods of time. Patients receiving TPN as their sole nutritional source for more than 1 or 2 weeks should also receive supplemental vitamin K. On the other hand, it has been suggested that vitamin K status should be assessed using serum dp-ucMGP to determine whether CKD 3–5D patients should receive vitamin K supplements. At present, the evidence supporting vitamin K supplements to correct high levels of serum dp-ucMGP or to reduce the risk of arterial calcification is not considered to be conclusive. On the other hand, in MHD patients, Westenfeld et al. [132] were able to reduce serum dp-ucMGP with vitamin K2 supplements in a dose-dependent fashion. After the supplements were terminated, during the washout period, serum dp-ucMGP increased again. Vitamin K2, which facilitates the carboxylation of MGP, may be a suitable therapeutic agent to decrease vascular calcification. Several clinical trials are currently underway to evaluate the effect of vitamin K supplements on vascular calcification and CV outcomes (e.g., iPACK-HD, NCT01528800; VitK-CUA NCT02278692; Vita VasK, NCT01742273). Because of the risks of treating patients with vitamin K, many physicians are now using the NOAC (new oral anticoagulants) instead of vitamin K. Care must be taken, because many of these nonvitamin K anticoagulants are primarily excreted by the kidney and might become toxic in advanced kidney failure.

#### Summary:

- Vitamin K acts at the hepatic, vascular, and bone level where it catalyzes the carboxylation of specific proteins that help to prevent excessive clotting and calcification of soft tissues, including blood vessels, and that promote normal bone metabolism.
- Data on the amount of vitamin K intake in CKD patients are lacking.
- Subclinical vitamin K deficiency, as determined by increased plasma PIVAK-2 and ucMGP levels, is frequent in CKD patients and is worsened by VKAs.
- Measurements in clinical laboratories of plasma PIVAK-2 and ucMGP are not yet routinely available.
- Vitamin K deficiency and the lack of clinically available testing for PIVAK-2 and ucMGP increase the risk of arterial calcification and of calciphylaxis.

Continued

- The effects of vitamin K supplements on vascular calcification are currently being investigated in several clinical trials.
- At this time the routine supplementation of vitamin K is not indicated for CKD, dialysis, and kidney transplant patients; recommendations may change pending the results of clinical trials.

## **Vitamin B1 (thiamine), physiology, biochemistry, and nutritional status in chronic kidney disease patients**

### **Vitamin B1 (thiamine) physiology and biochemistry**

It is stated that the syndrome of beriberi has been recognized for over 4000 years [133]. In 1911 an antiberiberi principle was discovered in rice bran extracts, and in 1934 the structure of thiamine was identified. Vitamin B1 or thiamine (Table 26.1) is a compound formed by the condensation of pyrimidine and thiazole rings. Thiamine forms esters with phosphate, functionally the most important of which are thiamine pyrophosphate (TPP), monophosphate, and triphosphate (TTP). Thiamine is rather labile and may be destroyed by heat, high pH (above 8), oxidants, and ultraviolet irradiation. Thiamine is abundant in only a few foods of animal and vegetable origin. These foods include lean pork, yeast, and legumes. Because thiamine is water soluble, foods cooked with water can be leached of significant amounts of thiamine. Thiamine is absorbed from the small intestine by active and passive processes. In plasma, thiamine is mainly bound to albumin. Most thiamine in the body is present as TPP. The availability or activity of thiamine is inhibited by, among other factors, alcoholic drinks, thiaminases, folate deficiency, and protein–energy malnutrition. Catabolism of thiamine produces many metabolites that are excreted in the urine. Erythrocyte and body levels of thiamine can be indirectly assessed by measuring the erythrocyte transketolase activity (ETKA), before (ETKA<sub>0</sub>) and after (ETKA<sub>s</sub>) stimulation by adding TPP to the assay [134]. The ETKA stimulation index ( $\alpha$ ETKA) (i.e., the ETKA with added TPP  $\times 100$ , divided by ETKA<sub>0</sub>, i.e., without added TPP) is a more sensitive indicator of thiamine deficiency. TPP can be measured directly with HPLC, which has become the preferred method for measuring thiamine status in many laboratories [135]. Both whole blood thiamine and RBC TPP, the active functional form of thiamine, are measured with HPLC.

TPP plays a key role in energy metabolism [136]. It is a coenzyme for a large number of chemical reactions involving, but not limited to, carbohydrate metabolism, including oxidative decarboxylation of  $\alpha$ -ketoacids and decarboxylation of alpha-ketoglutarate to succinyl-coenzyme A (CoA)

in the citric acid cycle. This is important for the production of gamma-aminobutyric acid, an inhibitory neurotransmitter in the brain. TPP is also the coenzyme for pyruvate dehydrogenase which catalyzes the conversion of pyruvate to acetyl-CoA. Hence, thiamine deficiency may impair lactate utilization and lead to thiamine-responsive lactic acidosis [137]. As indicated earlier, thiamine is a coenzyme for the transketolase reaction which is an integral part of the pentose phosphate pathway. Transketolase is found abundantly in myelinated structures of nervous tissues [138]. This may account for the peripheral neuropathy that occurs in beriberi. Thiamine deficiency has been associated with several syndromes involving the central and peripheral nervous systems, such as peripheral neuropathy and/or the Wernicke–Korsakoff syndrome in chronic alcoholism and in dry beriberi, and in cardiomyopathy with heart failure in wet beriberi. These clinical syndromes of thiamine deficiency are not often encountered today but are still occasionally observed (see next) [139–141]. Moreover, inborn errors of thiamine transporters are now well identified, and five phenotypes associated with these genetic disorders are described: megaloblastic anemia, deafness and diabetes in SLC19A2 defects, and peripheral neuropathy and encephalopathy in SLC19A3, SLC25A19, and TPK1 genetic defects [142]. Several medications may also interfere with thiamine metabolism or actions. They are summarized in Table 26.2.

### **Dietary vitamin B1 intake in chronic kidney disease patients**

Restriction of foods rich in potassium does not interfere with dietary thiamine intake. Thiamine intake has been reported to remain at or above the RDA when the protein intake is at least 40–80 g/d (see Table 26.2 from Stein et al. [15]). Among 210 CKD patients, thiamine intake averaged 136% of the recommended intake [16], but intake remained below the recommendation in 37% of the patients. However, Jankowska et al. [4] identified inadequate daily thiamine intake (i.e., below the EAR) in 62% of CKD patients, 58% of MHD patients, and 48% of kidney transplant recipients who were not receiving vitamin supplements. In CPD patients, 65% of the patients were below the EAR for thiamine, confirming previous reports. Wang et al. [17] reported an average daily intake of about 50% of the RDA in 242 CPD patients, both male and female. Their thiamine intake was independently related to total urea clearance and RRF, possibly because less efficient dialysis is associated with decreased protein intake. Also, Martin-Del-Campo et al. [18] found that approximately 30% of 67 CPD patients had a daily thiamine intake below the recommended intake. Eating habits influence the amount of vitamins ingested by CKD or maintenance dialysis patients, and this also appears to be

the case for thiamine. Of MHD patients, 73.7% who were in the habit of eating dinner, a meal associated with a better quality of ingested food (higher protein and lower lipid contents), met the recommended intake for thiamine as compared to 45.5% patients who often did not eat dinner [143]. These data also underscore the nutritional superiority of traditional foods and cooking in comparison to most processed foods. Bossola et al. [3] reported, from 3-day diet diaries, that 92% of 128 Italian MHD patients had a vitamin B1 intake below the RDI. Data from a 7-day food questionnaire obtained from seven MHD patients indicated that the intake of vitamin C, thiamine, riboflavin, and niacin was not different between the day of dialysis and an interdialytic day, but these findings are limited by the small number of patients studied [144].

### **Vitamin B1 (thiamine) nutritional status in chronic kidney disease, maintenance hemodialysis, chronic peritoneal dialysis, kidney transplant, and acute kidney injury patients**

The effects of CKD on thiamine metabolism remain unclear. In Sprague–Dawley rats after 5/6 nephrectomy, thiamine transporters were markedly decreased in the small intestine, heart, and liver when compared to sham-operated control rats, whereas plasma thiamine levels were not different between the two groups [145]. Thus intestinal absorption of thiamine and its availability at the organ level might be impaired in CKD. The ETKA stimulation index was found to be normal by Kopple et al. [146] in 15 nondialyzed advanced CKD patients who were receiving 1 mg/d thiamine HCl supplements. No relationship was observed between ETKA or the ETKA stimulation index and the level of GFR. In 33 adults with the nephrotic syndrome, erythrocyte TPP was normal [147]. Other investigators reported that the blood thiamine levels are usually in the normal range in MHD patients [148]. However, uremic toxins may impair thiamine function. In the early days of chronic dialysis therapy, Lonergan et al. reported a dialyzable compound in uremic serum that inhibited ETKA and suggested that it might be guanidinosuccinic acid [149]. This inhibitory effect of uremic sera was ameliorated by dialysis treatment. Sterzel et al. [150] reported that transketolase activity of nervous tissue was inhibited by uremic plasma, by cerebrospinal fluid from uremic patients and by a low molecular weight (MW) fraction (<500 kDa) of dialysate. Kopple et al. [146] did not find acute changes in ETKA observed during a single HD treatment. Kuriyama confirmed a low basal ETKA (ETKA<sub>o</sub>) and stimulated ETKA (ETKA<sub>s</sub>) in a group of 72 MHD, CPD, and nondialyzed CKD patients, even though they had high blood thiamine levels following

the ingestion of thiamine supplements [151]. These findings are consistent with a circulating inhibitor of ETKA in chronic kidney failure.

In 43 nonsupplemented MHD patients, Descombes et al. found low or marginal ETKA<sub>o</sub> in 56% of MHD patients, and an increased ETKA stimulation index in 21% of the MHD patients [152]. In ETKA<sub>o</sub> deficient patients, whole blood thiamine was normal. The functional deficiency was reversed with large amounts of thiamine hydrochloride (100 mg after each HD). In the same study, patients undergoing MHD with a polyacrylonitrile membrane dialyzer had lower ETKA<sub>o</sub> than those treated with cellulose acetate; these findings raise the question of a possible role of high hemodialyzer membrane flux as a cause of thiamine deficiency. Heinz et al. [153] reported that the HD procedure induces a greater decrease in plasma thiamine levels with high-flux versus low-flux membranes. Saka et al. [154] analyzed the thiamine status using HPLC before the first HD session in 241 incident MHD patients not receiving vitamin supplements. Whole blood thiamine levels were below the normal range in 12.4% of the patients and were inversely correlated with age and positively correlated with Barthel index (a physical function score), diastolic blood pressure, BMI, and hemoglobin. Surprisingly, using stepwise logistic regression analysis, the Barthel index remained the only variable associated with blood thiamine levels. In 100 MHD patients, Ubukata et al. [155] did not observe low serum thiamine levels in MHD patients, and only 18% of patients exhibited a post-HD decrease in serum thiamine. The prescribed membranes were high flux, but the prescribed blood flow was low ( $\leq 250$  mL/min). Jankowska et al. [156] found a significant decrease in whole blood TPP during the HD session (i.e., a decrease of 43.9% with a wide coefficient of variation, 71.5%). The TPP decrease was inversely correlated with the patient's body weight but not with the membrane flux. This is surprising because thiamine is bound to albumin in plasma. Despite the decrease in TPP during the HD session, only one patient had a blood TPP below normal. Thiamine intake and supplements were not found to be correlated with the whole blood TPP levels, casting doubts about altered intestinal absorption of thiamine in CKD patients as was suggested in the experiment on CKD rats mentioned earlier [145]. Coveney et al. [157] reported lower blood thiamine in patients treated with extended dialysis sessions when compared to patients treated by conventional dialysis. However, as reported in several previous studies, no patient had abnormally low blood thiamine. Hence, thiamine losses during the HD procedure and nutritional status of thiamine in chronic dialysis patients remain controversial.

Blumberg et al. [158], and Boeschoten and coworkers [32] reported thiamine deficiency in 50% and 26%, respectively, of CPD patients who were not receiving thiamine supplements. Losses of this vitamin into the peritoneal dialysate were identified but were substantially lower than the normal daily urine excretion of thiamine [32]. Jankowska et al. [159] also identified TPP in peritoneal effluent from 26 patients treated either with CAPD or automated peritoneal dialysis. The losses were low in most patients, independent of thiamine supplementation, but in two patients they were close to the RDA for thiamine. Analyzing the TPP losses during the peritoneal equilibrium test, the authors concluded that clearance of TPP was, to some extent, typical for smaller molecules. However, the amount of TPP in the 24-hour effluent was higher than in the plasma, independent of glucose transfer and convective transport, raising the possibility of active TPP transport by the peritoneal membrane or local synthesis. This is an important question which should be addressed in further research. Recently, in 75 AKI patients, serum vitamin B1 (thiamine) was found deficient only in 16% of the patients, much less than for vitamin B6 (67%), vitamin C (87%), and folate (33%) [160].

The question of functional vitamin B1 deficiency in the presence of normal thiamine levels was addressed in a recent study by Zhang et al. [161]. The authors measured both plasma and RBC thiamine and TPP levels using HPLC and ETKA in 16 CPD patients, 16 MHD patients, and 16 controls. They also assessed oxythiamine and oxythiamine pyrophosphate (OTPP), an inhibitor of TPP-dependent enzymes that accumulates in kidney failure. Plasma and RBC thiamine levels were increased in both CPD and MHD patients, whereas the RBC transketolase activity (ETKA<sub>0</sub>) was decreased in MHD patients by 41% compared to controls. Adding TPP in excess (i.e., an ETKA<sub>0</sub>) had no effect on ETKA in controls, but ETKA increased significantly in MHD patients, supporting the hypothesis of displacement of a competitive inhibitor by TPP. Plasma oxythiamine levels were increased 4-fold in the CPD patients and 15-fold in the MHD patients as compared to healthy controls. Oxythiamine decreased by 53% after a dialysis session. These data suggest that oxythiamine accounted for most of the ETKA inhibition, as reflected in the relationship between RBC OTPP and ETKA inhibition. However, *in vitro* RBC studies indicated that the inhibition was reversible; a high concentration of thiamine was able to reverse the reduced ETKA. These data support the thesis that there may be a discordance between normal plasma concentrations and impaired functional activity of a vitamin due to the accumulation of molecules that competitively inhibit the actions of the vitamin.

## Clinical significance of thiamine deficiency in chronic kidney disease patients

Clinical manifestations of thiamine deficiency have rarely been described in end-stage kidney disease (ESKD) patients. Beriberi was reported in two MHD patients decades ago [162,163]. Several cases of lactic acidosis, hyperglycemia, and compromised hemodynamics reversed by thiamine injections occurring early after kidney transplantation have been reported in adults [164,165] and in a child [140]. Case reports of Wernicke's encephalopathy are increasing in frequency. They are described in MHD and CPD patients but may often be overlooked because the classical triad of this syndrome (confusional state, ataxia, and ophthalmoplegia) is present in only 20% of cases [166–169]. In the report by Ueda et al. [169], typical pathologic lesions of Wernicke's encephalopathy were found in five patients who had been given such other diagnoses by clinicians as uremic encephalopathy, disequilibrium syndrome, dialysis dementia, or brainstem hemorrhage. Also, chorea has been reported in two cases of thiamine deficiency in MHD patients [170]. The same authors found thiamine deficiency in 10 MHD patients presenting with mental disturbances; 9 out of 10 recovered with intravenous thiamine supplementation [171]. Infection, surgery, and large glucose loads may increase the nutritional needs for thiamine, and precipitate clinical manifestations of thiamine deficiency.

Recently, treatment with large doses of thiamine and ascorbic acid in association with glucocorticoids (ATS) has been proposed to improve the outcomes in critically ill patients with such conditions as pneumonia [172] or septic shock [173,174]. See also the vitamin C (ascorbic acid) discussion later. The rationale for treatment with thiamine and vitamin C prescriptions is that these vitamins are frequently depleted in these conditions, and thiamine is critical for normal lactate metabolism, and vitamin C has important antioxidant and antiinflammatory properties and actions on neurotransmitter synthesis. The amounts of thiamine and vitamin C given to these patients were, respectively, 400 mg/d and 6 g/d for 4 days. Three retrospective "before/after" cohorts were studied using propensity scores. In the three studies, mortality was significantly reduced in the patients receiving ATS. The incidence of AKI did not differ between the treatment and control groups in the study by Sadaka et al. [174], and the need for renal replacement therapy was significantly decreased [173] or identical for ATS versus the control groups [172]. On the other hand, Litwak et al. [175] did not confirm a survival advantage with ATS in critically patients.

## Thiamine supplementation in chronic kidney disease, chronic dialysis, and kidney transplant patients

There is no specific guideline for thiamine supplementation in CKD 3–5D and CKD T1–5 patients in the recent KDOQI nutrition guidelines update except that the dietary vitamin intake of adults with CKD 1–5D and CKD T1–5 should be periodically assessed and multivitamin supplementation should be considered for individuals with inadequate vitamin intake. Also, CKD 5D patients who have inadequate dietary intake of vitamins for extended periods of time should be considered for multivitamin supplements [1]. Some investigators have recommended amounts of thiamine supplements for MHD patients ranging from 1 to 40 mg daily [152,176]. The thiamine intake from food is generally about 0.6–1.5 mg/d in advanced CKD, MHD, and CPD patients. The ETKA stimulation index and serum thiamine levels are usually normal in patients with CKD 3–5D. When thiamine deficiency is present, correction is readily obtained by feeding low quantities of thiamine. The Food and Nutrition Board recommended dietary allowances (RDAs) for thiamine for nonpregnant healthy adults are 1.1 and 1.2 mg/d, for females and males, respectively, and there is no reason to believe that the daily thiamine requirement for CKD 3–5D patients is lower than this amount. Although these patients may receive adequate thiamine from their ingested foods, their food intake not uncommonly is low, particularly when other morbid conditions are present, and as indicated earlier, thiamine deficiency has been reported in some CKD 3–5 patients. As recently suggested that oxythiamine accumulates in CKD and may act as a competitive inhibitor of thiamine. We, therefore, recommend the routine administration of a thiamine supplement of 1.2 mg/d for nondialyzed CKD 3–5, MHD and CPD patients (Table 26.4).

### Summary:

- Dietary vitamin B1 (thiamine) intake is often below the RDA in advanced CKD, MHD, and CPD patients.
- Discrepancies often exist in kidney failure patients between the measurement of normal serum or plasma concentrations of vitamin B1 and impaired functional tests (e.g., ETKA and the ETKA stimulation index) which are indicators of vitamin B1 inadequacy.
- Recent data suggest a competitive inhibition of ETKA by oxythiamine and possibly other compounds that accumulate in advanced CKD.

Continued

- In advanced CKD, MHD, CPD, or kidney transplant patients who develop unusual neurological symptoms, thiamine deficiency should be considered.
- Critically ill patients with AKI often have low serum levels of thiamine.
- Treatment of acutely and severely ill patients with a combination of thiamine, vitamin C, and glucocorticosteroids (ATS), which has been used to prevent or limit the severity of AKI and to decrease mortality, remains controversial.
- It is recommended that daily thiamine supplements equal to the RDA should be routinely prescribed to advanced CKD, MHD, and CPD patients.

## Vitamin B2 (riboflavin), physiology, biochemistry, and nutritional status in chronic kidney disease patients

### Vitamin B2 or riboflavin physiology and biochemistry

Riboflavin (vitamin B2) is an alloxazine derivative with an MW of 376.4 (Table 26.1). The main active riboflavin compounds are flavin mononucleotide (FMN, an alloxazine ring combined with ribitol and phosphate) and flavin adenine dinucleotide (FAD, the FMN molecule modified by the addition of an activated adenosine monophosphate). Riboflavin is modestly soluble in aqueous solutions, heat-stable, and photosensitive. It is present in many plant and animal products, such as milk, eggs, bread, cereals, lean meats, and broccoli [177]. An active sodium- and glucose-dependent absorption pathway for riboflavin occurs in the proximal jejunum and is important for the transport of small quantities of this vitamin. Large amounts of riboflavin are absorbed from the intestine by passive diffusion. Bile salts appear to facilitate intestinal absorption of riboflavin. After cellular uptake, riboflavin is transformed by the action of flavokinase and FAD synthetase to FMN and the more abundant FAD which act as cofactors to enzymes called flavoproteins. Riboflavin metabolites are excreted in urine. Flavoenzymes are involved in numerous oxidation–reduction reactions that are necessary for many metabolic pathways, including energy production. The erythrocyte glutathione reductase (EGR) activity without (EGR<sub>0</sub>) and with the saturation of this enzyme with FAD has been used to assess riboflavin status [134]. The ratio of EGR with FAD  $\times$  100 divided by EGR<sub>0</sub> indicates the EGR stimulation index ( $\alpha$ -EGR). The  $\alpha$ -EGR is a rather reproducible and sensitive test, a high  $\alpha$ -EGR indicating riboflavin deficiency. Riboflavin may be measured directly by a fluorometric method and by

HPLC, which has been used to study riboflavin in CKD patients [178]. Several medications may interfere with vitamin B2 metabolism or actions. They are summarized in Table 26.3.

### Dietary riboflavin (vitamin B2) intake in advanced chronic kidney disease, maintenance hemodialysis, and chronic peritoneal dialysis patients

With protein-restricted diets the daily intake of riboflavin is reported to be low with a 40 g/d protein diet and meeting the RDA with a protein intake of 60 or 80 g/d [15]. In the study by Chan et al. [16] in 210 nondialyzed CKD patients, 41% of the patients had an insufficient intake of riboflavin, a low intake that was confirmed at the same level by Jankowska et al. [4] in 50 nondialyzed CKD patients. These latter authors also found a low daily riboflavin intake in, respectively, 58%, 47%, and 15%, respectively, of MHD, CPD, and kidney transplant patients. Wang et al. [17] also found a low riboflavin intake in most CPD patients, independent of their RRF and the adequacy of their dialysis treatments. Martin-Del-Campo et al. [18] reported that 25% of 73 Mexican CPD patients had a low intake of riboflavin, and patients in the higher quartile of serum CRP levels had significantly lower intakes of riboflavin. Bossola et al. [3] examined 3-day diet diaries from 128 Italian MHD patients and reported a daily riboflavin intake below the RDI in 74% of the patients.

### Riboflavin (vitamin B2) nutritional status in advanced chronic kidney disease, chronic dialysis, and kidney transplant patients

Porrini et al. [179] reported increased  $\alpha$ -EGR (i.e., increased EGR stimulation index), indicating riboflavin deficiency, in many nondialyzed CKD patients prescribed a low-protein diet. The clinical significance of this finding remains unknown. Most studies showed normal or increased plasma riboflavin levels in MHD and CPD patients even when they are not prescribed vitamin supplements [32,152,180], notwithstanding the losses of riboflavin into peritoneal dialysate [32] and probably hemodialysate. However, Skoupy et al. found that 18.5% of CAPD patients had increased  $\alpha$ -EGR, indicating riboflavin deficiency [181]. On the other hand, riboflavin deficiency was not identified in 12 pediatric CPD and MHD patients who were not receiving vitamin supplements [182]. In MHD patients receiving multivitamin supplements and treated with standard or daily nocturnal HD sessions, no riboflavin deficiency was found even with the extensive dialysis treatments [183]. No clinical syndromes associated with riboflavin excess or deficiency have been reported in CKD or End-Stage Renal Disease (ESRD) patients.

### Riboflavin supplementation in chronic kidney disease, chronic dialysis, and kidney transplant patients

The recommended guidelines for riboflavin supplementation in CKD 3–5D and CKD T1–5 patients in the recent KDOQI nutrition guidelines for CKD are similar to those for thiamine [1] (Table 26.4): dietary vitamin intake of adults with CKD 1–5D and CKD T1–5 should be periodically assessed, and multivitamin supplementation should be considered for individuals with inadequate vitamin intake. CKD 5D patients who have inadequate dietary intake of vitamins for extended periods of time should be considered for multivitamin supplements [1]. Recommendations by other workers in the field vary from no riboflavin supplement [32,152,184] to an amount equivalent to the RDA [185,186], which is 1.1 mg/d for nonpregnant women and 1.4 mg/d for men. Low doses of riboflavin (1 mg/d) were sufficient to normalize the  $\alpha$ -EGR in CAPD patients [22]. For the rationale put forth for thiamine, we recommend a routine daily riboflavin supplement equal to the RDA for CKD 3–5D patients.

#### Summary:

- Dietary riboflavin (vitamin B2) intake is frequently reported to be below the RDA in advanced nondialyzed CKD, MHD, and CPD patients.
- Data regarding blood riboflavin (vitamin B2) levels in CKD and ESRD patients are conflictory. This may be partly due to discrepancies between the direct of measurements of plasma riboflavin concentrations and functional tests (e.g., the EGR stimulation index).
- No clinical syndromes related to riboflavin deficiency have been described in advanced CKD, chronic dialysis, or renal transplant patients.
- It is recommended that daily supplements of riboflavin equal to the RDA should be routinely prescribed to advanced CKD, MHD, and CPD patients.

### Vitamin B6 (pyridoxine) physiology, biochemistry, and nutritional status in chronic kidney disease patients

#### Vitamin B6 physiology and biochemistry

Reference is made to previous reviews of normal vitamin B6 metabolism and function [187,188]. Vitamin B6 is composed of three derivatives of the pyridine ring: pyridoxine, pyridoxal, and pyridoxamine. Some characteristics of vitamin B6 are listed in Table 26.1. Phosphorylation in the 5 position is necessary for the biological activity of vitamin B6.

Pyridoxal-5'-phosphate (PLP) and pyridoxamine-5'-phosphate are the active coenzyme forms. Pyridoxine is mainly found in plant foods, especially wheat bran, avocado, banana, lentils, walnuts, cooked soybean, and potatoes, and pyridoxal and pyridoxamine are primarily obtained from animal products; for example, tuna, raw chicken breast, and ground beef. These compounds are absorbed by a nonsaturable, passive process in the jejunum. These three vitamers are phosphorylated in the liver by pyridoxine kinase, which requires zinc and adenosine triphosphate. PLP is derived from the other vitamers by the action of FMN oxidase and is transported in plasma bound to albumin and in red cells bound to hemoglobin. The major repository of PLP is skeletal muscle, where it is bound to glycogen phosphorylase. In liver, PLP and the other phosphorylated forms of vitamin B6 are dephosphorylated by alkaline phosphatase, leading first to pyridoxal and then 4-pyridoxic acid (4-PA) by the irreversible action of a FAD-dependent aldehyde oxidase.

Functional tests have traditionally been utilized to assess for vitamin B6 deficiency. Erythrocyte glutamate oxaloacetate transaminase (EGOT) or glutamic pyruvate transaminase (EGPT) activity is measured in the basal state (EGOT<sub>0</sub>, EGPT<sub>0</sub>) and after stimulation by adding excess PLP. The ratio of the stimulated-to-basal activity is the activation coefficient or index ( $\alpha$ -EGOT and  $\alpha$ -EGPT). If stores of the coenzyme (PLP) are adequate, the addition of an excess of the coenzyme will have only a small effect on the apoenzyme activity, and the ratio will be close to 1.0. If there is deficiency of PLP, the apoenzyme will be stimulated by the addition of the coenzyme, and the index value will be substantially greater than 1.0 [189]. Currently, plasma levels of PLP and other B6 compounds are usually measured by HPLC [189]. Several factors are associated with higher or lower plasma PLP levels. People over 65 years have lower plasma PLP levels than younger individuals. Women have lower levels than men. One explanation for these findings could be differences in muscle mass. Plasma PLP levels are inversely correlated with dietary protein intake. Tobacco smoking decreases plasma B6 levels. Increased serum acute phase proteins and alkaline phosphatase activity and impaired renal function are associated with lower plasma B6 levels [190]. Also, many medicines interfere with the actions or metabolism of vitamin B6. Many of these medicines are taken by patients with CKD (Table 26.2). The intake of these medicines must be considered when evaluating studies of the dietary requirements for vitamin B6 or when prescribing vitamin B6 intake.

PLP is a coenzyme for more than 140 enzymatic reactions [191] and particularly for those enzymes involved with the metabolism of amino acids and

some lipids. PLP forms a Schiff base with the  $\epsilon$ -amino group of lysine in many enzymes. The Schiff base alters the charge on the rest of the PLP molecule and strongly increases its reactivity, particularly to other amino acids. Vitamin B6 is essential for gluconeogenesis by facilitating, among other mechanisms, transamination and glycogen phosphorylation, for niacin formation via the PLP-dependent kynureninase which transforms tryptophan to niacin, and for normal erythrocyte metabolism by acting as coenzyme for transaminase and influencing the hemoglobin affinity for oxygen. Vitamin B6 facilitates the synthesis of several neurotransmitters and modulates the actions of certain hormones through the binding of PLP to steroid receptors.

### Dietary vitamin B6 intake in chronic kidney disease patients

A high vitamin B6 intake does not appear to be associated with a lower CKD incidence in a large cohort of healthy subjects without CKD, in contrast to high intakes of folates and vitamins B12, C, and E [14]. Protein-restricted diets are not associated with low vitamin B6 intake (Table 26.3; [15]). In a recent study addressing the dietary micronutrient intakes in CKD, MHD, CPD, and renal transplant patients not receiving vitamin supplements, vitamin B6 intake was below the DRI in about 40%, 40%, 20%, and 30%, respectively, of these patients [4]. Vitamin B6 intake is often low in dietary surveys of CPD and MHD patients [158,176]. In CPD patients, Wang et al. [17] also reported inadequate intakes for B6 independently of RRF and dialysis adequacy. Martin-Del-Campo et al. [18] reported that 50% of 73 CPD patients have low intakes of vitamin B6. Dietary habits may influence the amount of vitamins ingested by CKD or maintenance dialysis patients. For example, lower intakes of vitamin B6 were found when MHD patients ingested meals of processed foods rather than home-prepared food [143].

### Nutritional status of vitamin B6 in advanced chronic kidney disease, chronic dialysis, kidney transplant, and acute kidney injury patients

Blunted weight gain was observed during a 4-week period in chronically azotemic compared to sham-operated rats and was significantly more pronounced in rats that were fed a vitamin B6-deficient diet as compared to a vitamin B6-surfeit diet [192]. Mydlik et al. found plasma PLP to be significantly decreased in adult patients with the nephrotic syndrome [147]. Podda et al. [193] reported significantly decreased blood PLP concentrations in 84 nephrotic patients as

compared to controls, and there was a positive correlation between the blood vitamin B6 levels and serum albumin. A high incidence of vitamin B6 deficiency in both adult and pediatric advanced CKD, MHD, and CPD patients has been observed in most, but not all studies. The use of red cell transaminase activity (EGOT<sub>o</sub> or EGPT<sub>o</sub>), rather than the activation coefficient or stimulation index ( $\alpha$ -EGOT and  $\alpha$ -EGPT), as the criterion for deficiency has been criticized because of the shortened life span of RBCs in CKD patients and the higher activities of some enzymes in younger erythrocytes [194]. Low plasma vitamin B6 levels have also been described in AKI patients especially in individuals with AKI-2 and AKI-3 who have high illness scores and are receiving renal replacement therapy (see Chapter 35: Metabolic Management and Nutritional Support in Acute Kidney Injury).

Studies that assessed vitamin B6 status by measuring plasma PLP concentrations also found decreased levels in most dialyzed and nondialyzed advanced CKD patients. In a recent systematic review of vitamin B6 status in MHD patients, Corken and Porter [195] reported a 33%–56% prevalence of vitamin B6 deficiency when low plasma PLP was used as the criterion for deficiency. However, this was not observed in a small cohort of children undergoing CPD and MHD; even those children who were not receiving vitamin supplements or enteral feeding had normal vitamin B6 concentrations [196]. In an adult cohort of 68 CKD stages 2–5 patients, of whom 18% were receiving vitamin B supplements, and 68 MHD patients treated with high-flux membrane of whom 48% were taking vitamin B supplements, plasma PLP, measured by HPLC, was in the normal range in 88% of the CKD patients and 97% of the MHD patients [197]. Busch et al. [198] analyzed vitamin B6 status with HPLC measurements of PLP in 48 CKD 2–4 patients, 72 MHD patients, 38 kidney transplant patients, and 141 healthy subjects. The MHD patients had received 10 mg of pyridoxine HCl after each dialysis session, whereas controls and the other patients were not taking vitamin B6 supplements. The CKD and kidney transplant patients had higher levels of plasma and RBC PLP compared to controls despite the absence of supplementation. MHD patients displayed decreased plasma PLP but not RBC PLP. Most strikingly, the vitamin B6 metabolite, 4-PA, was very high in plasma and RBC of the MHD patients which was probably due to the loss of renal function and possibly metabolism of the supplemental pyridoxine HCl. There was no relationship between the vitamin B6 status in plasma or RBC and the history of CV events. The authors questioned whether the PA accumulation was safe, and indeed a subsequent report has associated high levels of plasma PA with tingling hands, diarrhea, and tachycardia in MHD patients who were taking large doses of pyridoxine HCl such as 50 mg/d [199].

The removal of vitamin B6 by HD was invoked to explain the low plasma PLP in MHD patients [198]. However, whether much vitamin B6 is removed by HD is not clearly established. Lacour et al. [200] did not find PLP in spent hemodialysate obtained from low-flux HD. This is not surprising since PLP is largely bound to albumin. The magnitude of PLP clearance with high-flux membranes is confictory. Kasama et al. [201] observed a significant reduction in predialysis serum PLP in six MHD patients after they changed from cuprophane to cellulose triacetate dialyzer membranes, whereas Heinz et al. [153] did not find any difference in serum PLP with the same study design. No data are currently available on PLP clearances with convective techniques. Boeschoten and coworkers reported that the quantity of PLP lost into peritoneal dialysate, assessed by HPLC, is similar to the normal urinary excretion of vitamin B6 [32]. In another study, much lower losses of PLP were reported with peritoneal dialysis [202]. However, some additional PLP bound to proteins may be lost into peritoneal dialysate.

In 10 AKI patients treated for with continuous venovenous hemofiltration (CVVH) or hemodiafiltration, serum PLP decreased, and the calculated PLP loss was 80 nmol/day [203], the PLP clearance was about 49% of the urea clearance. In 75 AKI patients who were receiving Continuous Renal Replacement Therapy (CRRT) (mainly CVVH) with nutritional support, serum vitamin B6 was below the normal range in 67% of the patients [160].

### Clinical significance of vitamin B6 deficiency in chronic kidney disease

As in the general population, there is no obvious clinical syndrome of vitamin B6 deficiency that has been described in CKD patients. However, several abnormalities that are common in vitamin B6 deficiency are often present in advanced CKD or chronic dialysis patients. In experimental animals and in humans, vitamin B6 deficiency is associated with many alterations in immune function, including reduced numbers of blood granulocytes and lymphocytes, decreased lymphocyte maturation, reduced blastogenic response of lymphocytes to mitogenic stimuli, delayed cutaneous hypersensitivity, and decreased antibody production. B6 deficiency may play a role in the alterations of immune function in advanced CKD. Many years ago, Dobbstein et al. [204] were able to reverse decreased reactivity in mixed lymphocyte culture by giving MHD patients 300 mg/d of pyridoxine HCl for 2 weeks. Kopple et al. [205] found that a normal EGPT index of 1.25 or lower was maintained with much lower doses of supplemental pyridoxine HCl, 10 mg/d in MHD patients and 5 mg/d in advanced CKD and CAPD patients. Casciato et al. [206]

improved immunologic function of polymorphonuclear neutrophils and lymphocytes in eight MHD patients, most of whom had vitamin B6 deficiency, by giving 50 mg/d of pyridoxine hydrochloride for 3–5 weeks. Recently, Chen et al. [197] reported that plasma PLP and pyridoxal, alone or in combination, were negatively correlated with serum CRP and IL-1, supporting the link between vitamin B6 deficiency and inflammation in CKD. However, studies of the effects of vitamin B6 supplements on inflammatory markers in CKD patients are lacking. Vitamin B6 deficiency may also enhance the risk of oxalate formation and deposits (see the next paragraph and the section on vitamin C). In a randomized, blinded, prospective clinical trial in 26 MHD patients with symptoms of peripheral neuropathy, there was dramatic improvement of symptoms in 14 patients who received pyridoxine HCl, 60 mg/d, for 4 weeks, but not in 12 patients who received vitamin B12, 500 µg/d orally, even though the initial serum PLP was only slightly and not significantly lower than in controls [207]. However, no objective measurements of motor nerve conduction velocity were reported in this chapter.

## Vitamin B6 and oxalate metabolism in chronic kidney disease

Oxalate is a known uremic toxin [208]. Oxalate is normally excreted in the urine. Very little oxalate is degraded in vivo in humans. Ascorbic acid contributes importantly to oxalate synthesis (see the section on vitamin C), and vitamin B6 deficiency also plays a key role. Pyridoxine is the coenzyme for the transamination of glyoxylate to glycine (Fig. 26.4). Vitamin B6 deficiency, which is not uncommon in CKD, may contribute to increased oxalate formation and plasma oxalate levels. Hence, both decreased removal of oxalate because of impaired renal function and reduced vitamin B6 activity may increase plasma oxalate. Mydlik et al. [209] reported a close relationship between the vitamin B6 nutriture and serum oxalate levels in MHD patients (Fig. 26.5). Several attempts have been made to decrease plasma oxalate levels with pharmacological doses of pyridoxine HCl. Conflicting results were obtained. Tomson et al. [210] did not observe a significant decrease in plasma oxalate in 21 chronic dialysis patients treated for 4 months with pyridoxine HCl, 100 mg/d. In contrast, a 46% decrease in plasma oxalate was observed by Balcke et al.

FIGURE 26.4 Pathways for oxalate metabolism.

FIGURE 26.5 Negative relationship between plasma vitamin B6 concentrations and plasma oxalate concentrations in maintenance HD patients. HD, Hemodialysis. Source: Mydlik M, Derzsiova K. Vitamin B6 and oxalic acid in clinical nephrology. *J Ren Nutr* 2010;20:S95–102. Reproduced with permission from the Editot.

[211] in MHD patients after 1 month treatment with pyridoxine HCl, 600 mg/d orally or 600 mg three times per week intravenously after HD treatments. However, plasma oxalate levels remained elevated with treatment and in the supersaturation range as reported by Worcester et al. [212]. In a controlled but not randomized study, Costello et al. [213] were unable to reduce plasma oxalate levels after 6 months of treatment with 100 mg/d of pyridoxine HCl or after 4 weeks of therapy with 750 mg/d of pyridoxine HCl. The reason for these discrepant results is not clear. Descombes et al. [214] reported a high plasma oxalic acid level in 33 patients receiving high-flux dialysis and 50 mg of pyridoxine HCl after each dialysis treatment, indicating that current dialysis techniques and vitamin B6 supplementation are not sufficient to normalize plasma oxalic acid levels. Patients with type I or type II primary hyperoxaluria have been treated with various doses of pyridoxine (25–1000 mg/d), also with variable results [215]. Oxalate clearance with dialysis differs with different dialyzers and dialysis modalities; the most efficient ones are the high-flux membranes, such as polysulfone and hemodiafiltration [216]. Renal transplantation remains the most effective therapy for hyperoxalemia [217].

### Vitamin B6 supplementation in advanced chronic kidney disease, chronic dialysis, and kidney transplant patients

Many workers in the field agree that there is a need for routine pyridoxine supplementation in CKD, MHD, CPD patients, and nephrotic patients. Recommended supplemental pyridoxine HCl doses vary from 1.2 mg/d [176] to 50 mg three times/wk [214]. These recommended doses were not based on dose–response studies, and, therefore, the daily vitamin need might differ from these recommendations. Kopple et al. [205], in a dose-finding study, found that a supplemental pyridoxine HCl dose of 10 mg/d, which is 82.3% pyridoxine, maintained a normal EGPT index of 1.25 or lower in all MHD patients. Lower daily pyridoxine HCl doses did not reliably maintain EGPT indexes at or below 1.25 in people undergoing MHD. When advanced CKD and CPD patients received a pyridoxine HCl supplement of 2.5 mg/d, the EGPT fell to normal slowly and often decreased to barely within the normal range. These findings suggest that CKD and CPD patients may need a pyridoxine HCl supplement of 5.0 mg/d (4.1 mg/d of the pyridoxine base) to ensure that they have a normal EGPT index. When sepsis is present or patients are taking medicines that are vitamin B6 antagonists, a supplemental pyridoxine HCl dose of 10 mg/d may be needed for CKD and CPD patients as well as MHD patients. This study was limited by the fact that sample sizes in many of the groups studied at a given dose were rather small [205]. In CAPD patients, Ross et al. found the lowest pyridoxine HCl dose that normalized serum

PLP levels to be 10 mg/d [202]. Kopple et al. only studied the EGPT index as the indicator of B6 adequacy in these dose–response studies [205]. As indicated in this review, in CKD and chronic dialysis patients, various doses of pyridoxine HCl normalized one or more parameters of vitamin B6 status; and it would seem helpful to repeat these dose–response studies measuring, in addition to the EGPT or EGOT index, the actual vitamin B6 molecules in plasma as well as some of the other vitamin B6 function tests [206].

In eight children undergoing CPD, Kriley and Warady reported that 10 mg/d of pyridoxine HCl increased serum PLP to twice the normal control levels [218]; lower doses of pyridoxine HCl would probably be adequate for this pediatric population. It is important to remember that the pyridoxine HCl dose that engenders a normal serum PLP level or EGPT or EGOT index may not necessarily indicate the desirable daily dose. Such factors as synthesis inhibitors, altered binding or cellular transport, or discrepant intracellular concentrations, could alter the needed doses for vitamin B6 in renal failure. In the absence of evidence to the contrary, it seems sensible to accept normal plasma levels as an appropriate or criterion for determining the desirable daily vitamin B6 dose. In MHD patients, Mydlik et al. [219] recommended 20 mg/d of pyridoxine HCl to correct or prevent a decrease in RBC vitamin B6 levels that may occur after several months of EPO treatment. Again, this was not a dose–response study. By contrast, 60 mg of pyridoxine HCl after each dialysis session was associated with a decreased hematological response to EPO [220]. In renal transplant recipients, no pyridoxine dose studies have been conducted. Based on these foregoing data, we recommended a daily dose of 5 mg of pyridoxine HCl for nondialyzed CKD 3–5, CPD, and CKD T1–5 patients and 10 mg for MHD patients (Table 26.4). Vitamin B6 supplementation in CKD patients was addressed as with thiamine and riboflavin by the recent update of the KDOQI nutrition guidelines [1] and no routine vitamin B6 supplementation was recommended (Table 26.4). Vitamin B6 supplements have been recommended for AKI patients to prevent or treat B6 deficiency, especially in patients with AKI-2 and AKI-3 who have high illness scores and are receiving renal replacement therapy (see Chapter 35: Metabolic Management and Nutritional Support in Acute Kidney Injury).

Vitamin B6 has been given as piridoxilate, which is a vasodilator that has been used to treat coronary artery and peripheral circulatory insufficiency. This medicine can cause oxalate nephropathy and ESRD [221]. Very high doses of pyridoxine HCl (i.e., 200–600 mg/d) occasionally have been associated with peripheral neuropathy in patients without kidney disease [222]. Since advanced CKD patients have impaired ability to excrete metabolites of vitamin B6, it is possible that these metabolites might accumulate and interfere with the normal, active metabolites of vitamin B6. Indeed, 4-PA, the main metabolite of vitamin B6, is excreted

primarily in the urine and might be expected to accumulate in patients with kidney failure, particularly in those taking vitamin B6 supplements. Therefore until more information is available, caution should be exercised when prescribing very large doses of pyridoxine HCl to nondialyzed CKD and maintenance dialysis patients (perhaps 25–50 mg/d or greater) for extended periods of time.

#### Summary:

- Vitamin B6 deficiency is often observed in advanced CKD and chronic dialysis patients.
- Dietary vitamin B6 intake is often below the RDA in advanced CKD and chronic dialysis patients.
- Many but not all studies indicate that vitamin B6 deficiency, determined by serum or blood measurements, is not uncommon in advanced CKD and chronic dialysis patients who are not receiving vitamin B6 supplements.
- Vitamin B6 deficiency is difficult to identify from clinical symptoms.
- Vitamin B6 deficiency may engender inflammation, immune dysfunction, increased oxalate generation, and polyneuropathy.
- Vitamin B6 supplements have been recommended for AKI-2 and AKI-3 patients to prevent or treat vitamin B6 deficiency which is often present, especially if they have high illness scores and are receiving dialysis treatment.
- The quantity of dietary vitamin B6 and supplemental pyridoxine HCl necessary to prevent or correct vitamin B6 deficiency from dose–response studies appears to be greater than the RDA for vitamin B6 in normal individuals.
- Since advanced CKD, MHD, and CPD patients commonly show evidence for vitamin B6 deficiency by laboratory testing, and their daily vitamin B6 requirement appears to be greater than normal, it is recommended that these patients should be given routine supplements of pyridoxine HCl.
- Vitamin B6 supplements should be given as pyridoxine HCl, 5 mg/d for nondialyzed advanced CKD and CPD patients and 10 mg/d for MHD patients.

### Vitamin C (ascorbic acid), physiology, biochemistry, and nutritional status in chronic kidney disease patients

#### Vitamin C physiology and biochemistry

Vitamin C (ascorbic acid, [Table 26.1](#)) deficiency can cause scurvy. Vitamin C is oxidized to dehydroascorbic acid (DHAA) which possesses antiscorbutic

activity. Ascorbic acid is mainly found in fresh fruits (e.g., blackcurrant, strawberry, lemon, orange, and lime) and vegetables (e.g., broccoli, Brussels sprouts, cauliflower, and cabbage). Ascorbic acid in food can be degraded by heat or extracted in cooking water. Absorption of ascorbic acid is an active, energy-requiring, and saturable process in the proximal part of the small intestine. About 70%–90% of the usual dietary vitamin C intake is absorbed in the intestine, but this fraction decreases substantially when large loads of ascorbic acid are ingested. In plasma, vitamin C is not protein-bound and is present in a reduced form. Ascorbic acid enters the cell by active transport. The average half-life of ascorbic acid in normal adult humans is about 16–20 days. The body ascorbic acid pools are regulated by intestinal absorption, glomerular filtration, renal tubule reabsorption, and catabolism of this vitamin [\[223\]](#). Excess ascorbic acid is filtered at the glomerulus and excreted intact in the urine. The catabolic rate for ascorbic acid is directly related to the body pool size. Ascorbic acid can be oxidized to DHAA and then to a variety of compounds, including L-xylose, threonic acid, and oxalic acid that are excreted in urine. Oxalic acid constitutes 5%–10% of the ascorbic acid metabolites. The methods for measuring ascorbic acid have evolved from colorimetric methods, based on the reductive properties of ascorbic acid, to HPLC technology that is sensitive and specific [\[224\]](#). The oxidized form of ascorbic acid, the ascorbyl free radical, can be detected by electron paramagnetic resonance spectroscopy. Ascorbic acid can be measured in plasma, which reflects recent dietary intake, and in leukocytes, which gives a more accurate estimate of the total body pool of ascorbic acid. Women usually have higher plasma ascorbic acid levels than men; smokers and elderly individuals have lower plasma ascorbic acid values. The function of ascorbic acid is largely due to its reversible reducing power. For instance, ascorbic acid plays an important role in metal-catalyzed hydroxylations by reducing the metal catalyst and allowing the metal–enzyme complex to reconstitute after it is oxidized. Perhaps the most well-recognized activities of ascorbic acid are collagen synthesis via lysyl and prolyl hydroxylations, hydroxylation of peptidyl proline, and enhanced secretion of procollagen that contains hydroxyproline. Ascorbic acid is also important for carnitine synthesis, for hydroxylation of dopamine to form norepinephrine, for hydroxylation of tryptophan to form serotonin, and also for amidation of peptide hormones, intestinal iron absorption, and antioxidant protection of folate and vitamin E. Several medications may interfere with vitamin C metabolism or actions. These are summarized in [Table 26.2](#).

## Dietary vitamin C (ascorbic acid) intake in chronic kidney disease patients

Farhadnejad et al. [14] studied the incidence of CKD and its relationship to nutrient intake for 3.6 years in a large cohort of healthy subjects without CKD. The upper quintiles of the dietary intake vitamin C, as well as folates, vitamins B12 and E, magnesium, and potassium, were associated with a significantly lower incidence of CKD during the follow-up, which is opposite to the increased incidence of CKD in patients in the higher quintiles of sodium intake. Asghari et al. [225], in 1179 subjects with glucose intolerance who were followed for 3 years, found that the upper tertiles of dietary total antioxidant capacity and vitamin C intake were associated with a 40% lower incidence of CKD. Vitamin C intake in CKD patients has been more extensively studied than most other micronutrients. Dietary vitamin C is reported to be inversely correlated with protein intake (Table 26.3; [15]). In the early days of chronic dialysis treatment, the average ascorbic acid intake of MHD patients was reported by Sullivan et al. [226] to be 34 mg/d, whereas the RDAs for ascorbic acid are, respectively, 75 and 90 mg/d in normal nonsmoking female and male adults [48]. Allman et al. [176] showed a low spontaneous intake of vitamin C in their MHD patients (69% consumed less than two-thirds of the RDA). More recently, in an Italian cohort of adult MHD patients, vitamin C intake was found to be below the RDI in almost all patients [3]. Chan et al. [16] identified insufficient intakes for vitamin C in 22% of 210 CKD stages 4–5 patients. Jankowska et al. [4] reported low vitamin C intakes, below the DRI, in 48%, 67%, 55%, and 52% of nondialyzed advanced CKD, MHD, CPD, and kidney transplant patients, respectively. These findings of frequent low ascorbic acid intake in a large proportion of kidney transplant patients are in contradiction with Bohm et al. [227] who found that renal transplant recipients have a vitamin C intake equal to the RDA. Regarding CPD patients, the high prevalence of low vitamin C intake observed by Jankowska et al. [4] is similar to previous reports [17,18]. In children undergoing MHD and CPD, vitamin C intake was found to be 51% and 77% of the RDA, respectively [228].

Today, because low-potassium diets, which typically are also low in ascorbic acid containing fruits and vegetables, are frequently prescribed for advanced nondialyzed CKD and chronic dialysis patients, the intake of vitamin C-containing foods is likely to be reduced. Hence, restriction of foods high in potassium commonly reduces the intake of ascorbic acid and may predispose to vitamin C deficiency [229]. Among the prescribed restrictions in dietary intake for chronic dialysis patients, the reduction in potassium is the one

most likely to be adhered to [230], and this increases the risk of low vitamin C intake. Moreover, prolonged soaking and boiling of vegetables, which may be employed to reduce the potassium content of food, may leech out or degrade ascorbic acid. Hence, ingesting the RDA for vitamins will depend on many factors, including the dietary prescription and the patient's adherence to the prescription, appetite, medicinal intake (see Table 26.3) and superimposed illnesses (see next). As recommended in the KDOQI CPGs for nutrition in CKD: 2020 update [1], a registered dietitian nutritionist or an international equivalent is the key person to evaluate the nutritional intake and status of the CKD and ESRD patients. This person should alert the patient and the nephrologist if the patient's vitamin needs are not being met.

## Vitamin C nutritional status in advanced chronic kidney disease, chronic dialysis, kidney transplant, and acute kidney injury patients

Advanced CKD and nephrotic patients are usually reported to have lower serum vitamin C levels as compared to healthy controls. Rajbala et al. [231] found decreased serum vitamin C in 45 children presenting with the nephrotic syndrome. This was confirmed by Fydryk et al. [232] who found decreased blood vitamin C during relapse of steroid-dependent nephrotic syndrome in 18 children. Vitamin C and E status were studied in 29 nephrotic patients and compared to 25 patients with hematuria [233]. Plasma vitamin C and the plasma ascorbate/vitamin E ratio were significantly lower in the nephrotic patients. Marumo [184] surprisingly found low plasma ascorbic acid levels in patients with mild-to-moderate CKD but not in nondialyzed advanced CKD patients or MHD patients. In contrast, Clermont et al. [59] found decreased plasma vitamin C levels with an increased ascorbyl-free radical/ascorbic acid ratio in advanced CKD patients. Intravenous furosemide increases urinary vitamin C excretion in CKD patients [234]. Gillis et al. [235] reported significantly lower plasma ascorbic acid levels, measured by HPLC, in 30 CKD stages 3–5 patients (average  $eGFR = 22.4 \pm 12.6$  mL/min/1.73 m<sup>2</sup>) compared to 20 hypertensive subjects without CKD. Bohm et al. [227] reported normal plasma vitamin C concentrations in renal transplant recipients. In 51 nonvitamin supplemented CKD stages 3–5 patients and 50 MHD patients, compared to 38 healthy controls, Gondouin et al. [236] found significantly lower plasma ascorbic acid levels, assessed by HPLC, in the CKD patients as compared to the controls. The MHD patients had significantly lower vitamin C plasma levels than the CKD patients.

In the early days of MHD treatment, Sullivan and Eisenstein described ascorbic acid deficiency in MHD

patients [226]. Later reports confirmed a high prevalence of vitamin C deficiency in MHD and CPD patients who were not given vitamin C supplements [32,59,158,176,237,238] and even in some patients receiving such supplements [152]. However, Tarnagel et al. [239] found normal vitamin C levels in 65 non-supplemented patients who had undergone MHD for a mean of 48.7 months. Ramirez et al. [148] monitored plasma ascorbic acid levels in MHD patients for 1 year after discontinuing vitamin C supplements. A dramatic decrease in plasma ascorbic acid was observed, but no patient reached a deficient level. Mydlik et al. [240] found normal plasma vitamin C levels in 32 CAPD patients not receiving ascorbic acid supplements. More recently, Zhang et al. [241] reported that 64% of 284 MHD and CAPD patients manifested deficiency or insufficiency for vitamin C, as determined by low plasma ascorbic acid levels. Sirover et al. [242] determined that 38% of a cohort of 203 MHD patients had plasma ascorbic acid values, measured by HPLC, below  $30 \mu\text{mol/L}$ , which is below normal levels, even though 52% of the patients were prescribed vitamin C supplements. Importantly, Deicher et al. [243] studied the relationship between ascorbic acid level and the occurrence of adverse cardiovascular events (MACE) and mortality in 138 prevalent HD patients during a 30-month follow-up period. Lower ( $<32 \mu\text{Moles/L}$ ) and middle ( $32\text{--}6 \mu\text{Moles/L}$ ) tertiles of vitamin C were significantly associated with MACE and CV mortality when compared to the group of patients in the upper tertile of vitamin C.

Ascorbic acid is a small MW, nonprotein-bound molecule, which is readily dialyzable. Bohm et al. [227] measured the amount of vitamin C in dialysate and found it to range from 92 to 334 mg per treatment; there was a 50% decrease in plasma ascorbic acid during an individual HD treatment and a return to predialysis levels by 44 hours. Hultqvist et al. [237] found a 40% decrease in plasma ascorbic acid during a 3-hour HD treatment. More recently, Sirover et al. [242] reported a 60% decrease of ascorbic acid in eight patients between the start and end of an HD session. Morena et al. [244] studied the effect of convection on vitamin C losses during paired-filtration. On average, 19 MHD patients lost 66 mg of ascorbic acid during the hemodiafiltration session, with one-third of these losses related to convection. Concerning peritoneal dialysate, 56 mg of ascorbic acid were recovered during a 24-hour PD cycle [32]. According to Mydlik et al. [240], the peritoneal transfer of ascorbic acid is affected by the dialysate glucose concentration. Ascorbic acid losses into peritoneal dialysate during CAPD were  $136.4 \mu\text{mol}$  during 6 hours of PD with 1.5% glucose in dialysate, and  $175.8 \mu\text{mol}$  during 6 hours of PD with 2.5% dialysate glucose. These impressive decreases in plasma ascorbic acid during

HD and the substantial recoveries of ascorbic acid from hemodialysate and peritoneal dialysate probably reflect the fact that ascorbic acid is not protein-bound in plasma and that normal plasma ascorbic concentrations tend to be high in comparison to other vitamins. In 75 AKI patients who were receiving CRRT (mainly CVVH) with nutritional support, serum vitamin C levels were below the normal range in 80% of the patients [160].

### Scurvy in chronic kidney disease patients

The foregoing data indicate that low plasma ascorbic acid levels are common in MHD and CPD patients who do not receive vitamin C supplements, but scurvy is seldom described in these patients. Ihle and Gillies reported a case of scurvy in an MHD patient in 1983 [245]. The patient manifested cutaneous symptoms (pruritus, bruising, and ecchymoses), impaired platelet function, a low vitamin C intake, and decreased plasma and leukocyte ascorbic acid levels. The defect in platelet function was similar to that reported with scurvy. Treatment with 1 g of vitamin C per day for a few days rapidly corrected the ecchymoses, prolonged bleeding time, and platelet dysfunction. Fatigue and periodontal lesions are frequent in dialysis patients, and their relationship to the frequent occurrence of vitamin C deficiency had not been thoroughly addressed until a few years ago [246]. Raimann et al. [247] reported a significantly higher prevalence of periodontal disease and teeth losses in MHD patients with serum ascorbic acid levels  $<10 \mu\text{mol/L}$  compared to patients with serum ascorbic acid above this level. More recently, scurvy has been occasionally described in both MHD and CPD patients [248–250].

### The oxalate burden in chronic kidney disease

As shown in Fig. 26.4, oxalate is a metabolic end product of ascorbic acid. It is an admitted uremic toxin [208] (see also the section on vitamin B6). In normal humans, urinary excretion of oxalate increases when they are fed an ascorbic acid load. However, the relationship between ascorbic acid intake and urinary oxalate excretion is not linear, and only a fraction of the ascorbic acid ingested is normally recovered in the urine as oxalate [251]. Recently, increased urinary oxalate excretion has been identified as an independent risk factor for CKD progression in CKD stages 2–4 [252]. Plasma oxalate concentrations are almost always increased in nondialyzed advanced CKD and chronic dialysis patients [212,253]. The increase in plasma oxalate becomes statistically significant when GFR falls below  $30 \text{ mL/min}$  [254]. In kidney transplant recipients

who underwent kidney biopsies during the first 3 months after transplantation, Kelly et al. [255] observed oxalate crystal deposits in 19.4% of the grafts. Higher serum creatinine, diabetes mellitus, and dialysis vintage were associated with these oxalate deposits. Plasma oxalate is correlated with serum creatinine [217] and may be increased several times above normal values in chronic renal failure patients—and close to the levels found in primary hyperoxaluria. Calcium oxalate deposits are described in several tissues in advanced CKD patients and appear to be most pronounced in kidneys, heart, blood vessels, thyroid gland, and skin and to increase with the duration of MHD therapy [256]. Mydlik et al. [240] reported increased plasma oxalic acid in 32 CAPD patients [ $23.6 \pm 7.4 \mu\text{mol/L}$  (SD); normal range,  $2\text{--}5.5 \mu\text{mol/L}$ ] even though these patients displayed a large peritoneal clearance of oxalate. In 15 MHD patients who also had increased plasma oxalate [ $40.3 \pm 9.8 \mu\text{mol/L}$  (SD)], oxalate clearance was greater with postdilutional hemofiltration (oxalate clearance, 74.2% of urea clearance) than with conventional HD (oxalate clearance, 58.1% of urea clearance) or postdilutional hemodiafiltration (oxalate clearance, 69% of urea clearance) [257]. In children, there appears a large discrepancy between dialysis oxalate clearances in those undergoing CAPD (7.14 mL/min,  $n = 15$ ) and MHD (115.6 mL/min,  $n = 10$ ). Nonetheless, because CAPD is conducted almost continuously, whereas MHD is performed for only about 12 h/week, the weekly elimination of oxalate was similar with these two treatments, and blood oxalic acid levels remained high and not different between the two groups [258]. A serum oxalate level  $>30 \mu\text{mol/L}$  has been proposed as the threshold that indicates calcium oxalate supersaturation in plasma [259].

There is strong evidence that a high vitamin C intake may contribute to hyperoxalemia and oxalate deposition in soft tissues of CKD patients. Oxalate accumulation with even low doses of ascorbic acid is related to the reduced GFR. With increased intake of ascorbic acid, the oxalate subsequently produced cannot readily be excreted in urine. Unlike in normal individuals who can tolerate much higher intakes of ascorbic acid without oxalate accumulation, the oxalate levels in advanced CKD and chronic dialysis patients will increase with these doses. In MHD patients, plasma oxalate levels increased with oral supplementation of 0.5–1 g/d of ascorbic acid; cessation of ascorbic acid supplements resulted in a decrease in plasma oxalate [260]. The calcium oxalate saturation threshold was exceeded in 7 of 18 patients (40%) during the course of 6 months of ascorbic acid therapy, 500 mg/week [261]. Ott et al. [262] observed bone oxalate deposits in a bone biopsy from a patient who had undergone MHD for 23 years and who had ingested 2.6 g/d of ascorbic acid for 7 years. A bone

biopsy in the same patient obtained before commencing ascorbic acid supplements showed no evidence of bone oxalate deposits. Calcium oxalate deposits in kidneys and pancreas was reported in a pediatric patient with the hemolytic uremic syndrome (HUS) who received 500 mg/d of ascorbic acid by parenteral nutrition for 3 months [263]. Hyperoxalemia is also associated with ascorbic acid supplementation in CPD patients [264]. Severe oxalate crystal deposits were found in the retina associated with proliferative retinopathy in a nondiabetic CPD patient who was taking over-the-counter purchased ascorbic acid, 4 g/d [265]. The patient's serum oxalate was  $187 \mu\text{mol/L}$  (normal serum oxalate,  $<1.7 \mu\text{mol/L}$ ). Certain types of bariatric surgery with gastric bypass procedures present a risk for increased intestinal oxalate absorption, and higher vitamin C intakes in this context may trigger oxalate nephropathy [266]. The role of vitamin B6 deficiency and sufficiency in oxalate metabolism is described in the section on vitamin B6.

### Vitamin C and anemia management in chronic kidney disease

The high prevalence of erythropoiesis stimulating agent (ESA) resistance, especially of inflammatory origin, and the quest to reduce the costs of ESA therapy for nondialyzed advanced CKD and chronic dialysis patients have led to many studies to improve the hemopoietic response to ESA. Since ascorbic acid ingestion enhances the intestinal absorption of iron, there is much interest concerning the potential value of ascorbic acid as adjuvant therapy to ESA particularly in MHD and CPD patients who have EPO-resistant anemia. Tarnig et al. [239] reported that in MHD patients who were hyporesponsive to ESA, had normal plasma vitamin C levels, and were treated with 300 mg of vitamin C given at the end of each dialysis session for 8 weeks, the hematocrit and transferrin saturation increased, even though the dosage of ESA decreased. However, only one-half of these patients had a positive response to vitamin C treatment. From the receiver operating characteristic analysis, the predictors of response to vitamin C were a combination of transferrin saturation below 25% and erythrocyte-zinc protoporphyrin level above 105 mmol/mol heme. Plasma oxalate levels increased slightly, but not to a statistically significant degree during vitamin C therapy. In past decades, many studies have indicated that vitamin C administration reduces anemia in renal failure. A metaanalysis identified 157 reports, but only six of these reports fulfilled the selection criteria for critical analysis [267]. The authors concluded that vitamin C, between 200 and 500 mg three times per week,

increases the transferrin saturation coefficient and decreases ESA needs. However, the long-term safety of such treatment was not addressed in this report, and oxalate supersaturation might have been reached in significant numbers of patients with these dosages [261]. In another metaanalysis for therapy of ESA resistance, only two studies met the selection criteria and showed a lack of benefit of vitamin C supplements. The KDIGO guidelines on anemia management do not recommend such adjuvants as folates or vitamin C with ESA therapy [268]. See also Chapter 38, Nutrition and Anemia in Chronic Kidney Disease.

### Vitamin C, inflammation, oxidant stress, and endothelial dysfunction in chronic kidney disease

In a crossover study, Zhang et al. [269] reported a significant decrease in plasma high-sensitivity CRP and a significant increase in plasma prealbumin after 3 months of vitamin C supplementation in 100 MHD patients, whereas serum albumin, hemoglobin, and the EPO-resistance index did not change. After vitamin C was stopped, plasma CRP and prealbumin returned to the initial levels. In a randomized double-blind trial in 151 MHD patients, Biniaz et al. [270] observed a significant reduction in serum CRP in the treated patients who were given 250 mg of ascorbic acid intravenously thrice-weekly. Morena et al. [244] found markers of oxidant stress to be significantly higher in MHD patients as compared to healthy subjects. The authors attributed the increased oxidant stress to significantly lower plasma vitamin C concentrations and the vitamin C losses during HD. Vitamin E could not account for these differences, because the vitamin E levels were not different between the two groups. Other studies with supplemental vitamin C show conflicting results with regard to effects on the patients' oxidation status, and no study of vitamin C supplements has addressed clinical outcomes of the patients. Interesting data have been published indicating beneficial effects of vitamin C on endothelial dysfunction that occurs not uncommonly in advanced CKD patients [271]. A study in patients with advanced CKD who were not receiving dialysis (mean GFR, 22 mL/min/1.73 m<sup>2</sup>) found low plasma vitamin C levels as compared to 30 hypertensive patients with normal GFR [235]. One single large intravenous dose of vitamin C (2000 mg) significantly reduced ADMA in the patients with advanced CKD, but not in the patients with hypertension. Central blood pressure decreased in both groups, but the flow-mediated dilation (FMD) did not. In children with CKD who were receiving a daily dose of vitamin C, 250 mg/d,

the carotid intima-media thickness decreased significantly, but FMD did not change [272]. Also, in a metaanalysis, including 19 trials, the relative risk of radiocontrast-induced nephritis (CIN) was reduced to 0.69 (95% CI, 0.49–0.82;  $P = .0005$ ) by adding vitamin C versus saline [80]. However, vitamin C alone or combined with *N*-acetylcysteine was not more effective at preventing CIN than *N*-acetylcysteine alone. These data concerning endothelial dysfunction and vitamin C treatment are encouraging. But the safety of such large doses of vitamin C, particularly with regard to the risk of hyperoxalemia and acidemia, needs to be established before such doses can be recommended.

### Vitamin C in critically ill patients

The association of vitamin C, thiamine, and steroids (ATS) has been recently studied in critically ill patients. See also the discussion on vitamin B1 (thiamine) earlier. The use of vitamin C per se in intensive care and cardiac surgery has been analyzed in a recent metaanalysis that was inconclusive regarding its benefit [273]. It is also questionable whether such high doses of acid ascorbic are safe. A case of oxalate nephropathy has been reported in a woman hospitalized with severe burns who received 101 g of vitamin C intravenously in 18 hours [274]. She died with AKI and lactic acidosis, and her autopsy confirmed oxalate nephropathy. In another case a 57-year-old woman who was in septic shock due to legionella pneumonia developed AKI was treated with CRRT. A kidney biopsy was performed after 72 days of persistent anuria, and oxalate nephropathy was identified [275]. The cumulative dose of vitamin C that she had received was 30 g over 2.5 months, which is much closer to what is recommended for ATS therapy.

### Vitamin C supplementation in advanced chronic kidney disease, chronic dialysis, and kidney transplant patients

Many studies suggest that MHD and CPD patients are at risk for vitamin C deficiency if they do not take additional ascorbic acid, and various amounts of daily ascorbic acid supplements have been recommended. The combination of insufficient dietary intake and dialysate losses of vitamin C appears to be the cause of deficiency. Foods that are rich in vitamin C are often proscribed because of the high potassium content. There is no clear evidence that the dietary vitamin C requirement or the amount necessary to maintain normal plasma ascorbic acid levels is increased in chronic dialysis patients. Indeed, the lack of urinary vitamin C excretion will to some extent offset the

dialysate losses. On the other hand, larger doses of vitamin C have been associated with increased oxalate concentrations in plasma and possibly soft tissues. It is possible that the ascorbic acid clearance with high-efficiency and/or high-flux hemodialyzers increases the dietary requirement for vitamin C. However, considering the small size of ascorbic acid (MW, 176), it is not likely that highly permeable dialyzers will markedly increase dialysis losses of vitamin C. At the present time, it is recommended that nondialyzed CKD 3–5, MHD, CPD, and kidney transplant patients be prescribed the RDA for ascorbic acid for nonpregnant, nonlactating adults, which is 75 mg/d for women and 90 mg/d for men (Table 26.4). This recommendation is consistent with the recent KDOQI nutrition in CKD guidelines, except that because low vitamin C intake is so prevalent and low serum vitamin C concentrations are so common, we recommend that the RDA for ascorbic acid be routinely supplemented to advanced CKD, MHD, and CPD patients [1] (Table 26.4). The low dietary vitamin C intakes in kidney transplant patients suggest that they should either be given supplemental vitamin C or monitored closely for vitamin C deficiency.

#### Summary:

- Vitamin C deficiency, as indicated by low plasma ascorbic acid concentrations, is very common in advanced CKD and chronic dialysis patients who do not take vitamin C supplements. Association with hard outcomes in HD patients has been reported.
- Low vitamin C intake, which is at least partly due to the need for CKD patients to eat potassium-restricted diets, and the losses of ascorbic acid during the dialysis procedure appear to be major contributors to the high prevalence of vitamin C deficiency in these individuals.
- Scurvy is infrequently described in CKD patients, but the long-term effects of subclinical vitamin C deficiency in CKD patients are unknown.
- Although some but not all reports have been encouraging reports, vitamin C supplements are not part of the KDIGO recommendations for anemia management for CKD patients who are receiving erythropoiesis stimulating agents.
- Whether ascorbic acid has antiinflammatory and antioxidant effects and may improve endothelial dysfunction in CKD and chronic dialysis patients requires more research.
- Critically ill patients with AKI often have low serum levels of vitamin C.
- The treatment of acutely and severely ill patients with vitamin C or a combination of vitamin C, thiamine, and glucocorticosteroids (ATS) to prevent or limit the

Continued

severity of AKI and to decrease mortality remains controversial.

- Vitamin C may be effective for preventing CIN.
- Large doses of vitamin C may induce oxalate nephropathy and provoke AKI.
- Vitamin C supplements with 75 mg (women) and 90 mg (men) are recommended for nondialyzed advanced CKD, MHD, and CPD patients because of the restricted potassium diet and the losses of ascorbic acid during the dialysis procedure.
- Large doses of vitamin C should be avoided in CKD, chronic dialysis, and AKI patients because of the risk of oxalic acid toxicity.

## Folate (vitamin B9), physiology, biochemistry, and nutritional status in chronic kidney disease patients

### Folate physiology and biochemistry

Folate refers to a family of structurally related compounds that have pteroylglutamic acid at its core and serve major metabolic functions in the acceptance, redox processing, and transfer of one carbon (including methyl, formyl, methylene, and methenyl groups). Folic acid, which is pteroylmonoglutamic acid, is seldom found in nature or in food form, but because it is chemically stable and inexpensive, it is commercially synthesized and used as a vitamin supplement and as a fortificant in foods. Pteroylglutamic acid is composed of three subunits: a pteridine moiety, para-aminobenzoic acid, and glutamic acid (Table 26.1). Most naturally occurring food folates are pteroylpolyglutamates that contain from one to six additional glutamates that are joined to the gamma-carboxyl of glutamate. Reduced forms of folic acid are present both in foods and in the human body, usually as tetrahydrofolate (THF). Folates are found in many foods, including yeast, liver, meats, green vegetables, and fruits. Very sensitive to oxidation, folates are readily destroyed by extensive cooking and by food processing such as canning or refining [276]. Intestinal absorption occurs mainly in the proximal one-third of the small intestine. Polyglutamates require the action of conjugases, present in the brush border of enterocytes, to be transformed to folate monoglutamates, such as 5-methyl-THF, formyl-THF, or dihydrofolates. Another enzyme, the glutamate carboxypeptidase II anchored in the intestinal brush border, participates in polyglutamate catabolism. Devlin et al. [277] identified an H475Y DNA variant coding for this enzyme; low folate levels and hyperhomocysteinemia are associated with a 53% reduction of the enzyme activity. Cellular transport relies on specific folate membrane receptors, carriers, and cellular exit pumps. Folates are stored in the body as

polyglutamates and require the action of conjugases, which are present in many tissues, to yield the biologically active monoglutamate form. However, polyglutamates may have physiological actions themselves. Actions of conjugases can be inhibited by various substances, including medicines. Indeed, many medicines may inhibit the actions of folate, including ones that are commonly prescribed for CKD patients (Table 26.2).

Folate in plasma is mainly free or loosely bound to nonspecific carriers. Delivery of folate to tissues requires a specific cell membrane receptor protein. Also, vitamin B12, which like folate is involved in transmethylation reactions, is necessary for cellular transport and storage of folate. Excretion of free folate and metabolites of folic acid occurs in urine and bile. A folate enterohepatic cycle helps to preserve the body pool of folates and is impaired by alcohol consumption. Folate nutriture is assessed mainly by measuring serum, plasma, or red cell folate levels with competitive binding protein assays that can detect nanogram quantities of 5-methyl-THF [278].

The fundamental action of folate can be summarized as one-carbon unit transfers [276]. Folic acid is required for DNA synthesis. The 5,10-methylene THF [requiring the vitamin B12-dependent transmethylation of homocysteine

(Hcy)–methionine] delivers its methyl group to deoxyuridylylate, which is transformed to thymidylate and is necessary for DNA synthesis. A defect in this step in DNA synthesis leads to megaloblastosis, which occurs in all replicating cells in the body but is most striking in bone marrow cells. Folate plays a role in amino acid metabolism, particularly for those amino acids that are methyl donors or receivers, including the interconversion of glycine and serine, the transformation of Hcy to methionine (Fig. 26.6), and the conversion of histidine to glutamic acid. Moreover, folate is required for purine synthesis in the methylation of transfer RNA. Unlike vitamin B12, folate is not involved in myelin synthesis, and, therefore, folate deficiency does not cause neurological disease.

### Dietary folate intake in chronic kidney disease

The relationship between CKD and folate intake is complicated, because food fortification programs have been implemented in a majority of western countries, and it, therefore, is hard to both assess dietary folate intakes in different populations and to compare the differences in folate intake from peoples who do and do not receive folate fortification. As indicated earlier, Farhadnejad et al.

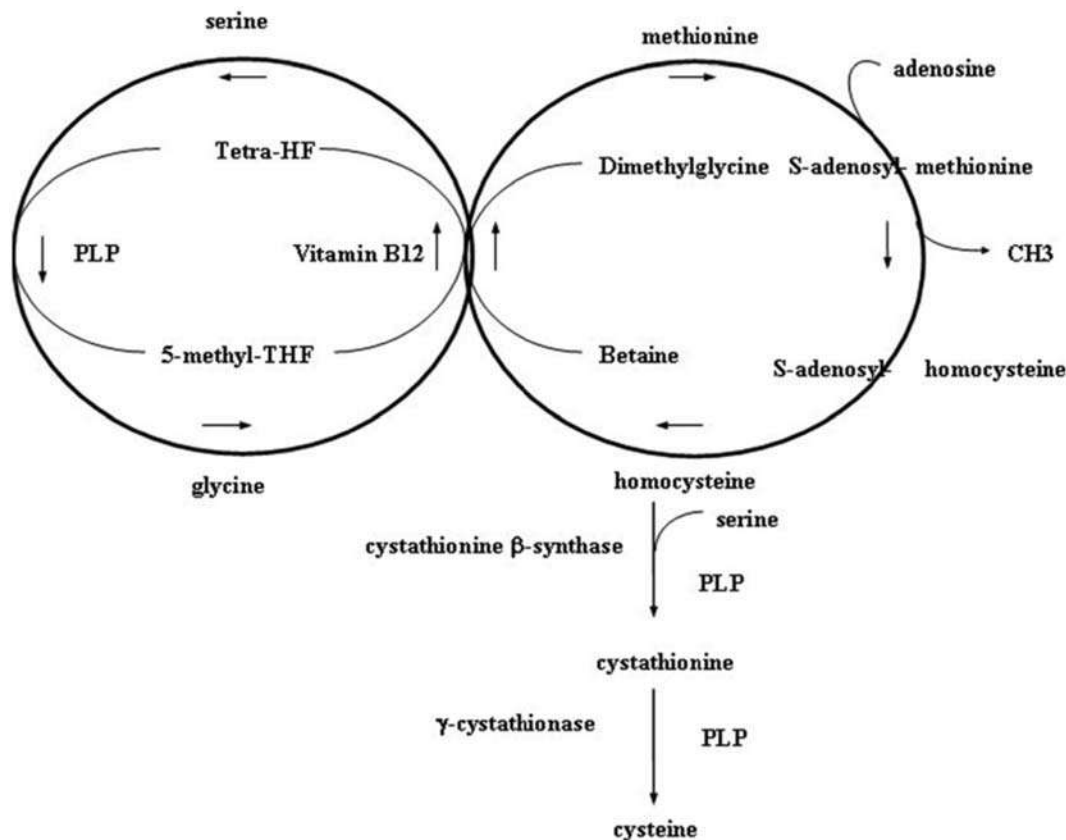

FIGURE 26.6 Role of folic acid, vitamin B12 and B6 in methionine–homocysteine–cysteine metabolism.

[14] reported that in a large cohort of healthy subjects followed for 3.6 years, the incidence of CKD was significantly lower in patients who were in the upper quintile of folate intake. The patients with a lower CKD incidence were also in the upper quintiles for vitamins C, B12, and E and magnesium and potassium intake. Dietary folate tends to be low with the protein-restricted diets commonly prescribed for nondialyzed CKD patients (Table 26.3; [15]). Hassan et al. [279] reported a direct relationship between daily folate intake and both the GFR and the potassium intake, which is also commonly reduced in advanced CKD patients. In a large cohort of CKD stages 4–5 patients, Chan et al. [16] found that folate intake was below the RDA recommendations in 68% of the patients. A high prevalence of low folate intake in 72% of these patients was confirmed by Jankowska et al. [4]. In this latter study, folate intake was also analyzed in MHD, CPD, and kidney transplant patients, and it was found to be below the EAR in 84%, 92%, and 77% of these individuals, respectively. Folate intake is reported to be inadequate in most CPD patients [17,18] and especially in those patients with little or no RRF and/or low peritoneal urea clearance [17].

### Folate nutrition in advanced chronic kidney disease, chronic dialysis, kidney transplant, and acute kidney injury patients

Bayer et al. [280] unexpectedly found low serum folic acid levels in 44% of 31 patients who had secondary thrombotic microangiopathies without obvious cause. The significance of this finding is not known according to the authors. Folic acid metabolism is altered in renal failure. The intestinal absorption of THF is impaired in experimental animals with advanced CKD. Said et al. [281] showed that azotemic rats had significantly lower absorption of 5-methyl-THF than sham-operated controls. Using the technique of perfusing an in vivo everted jejunal sac, these authors found that predialysis sera obtained from MHD patients suppressed intestinal absorption of 5-methyl-THF, whereas postdialysis sera caused significantly less suppression. In rats with chronic kidney failure, Bukhari et al. [145] demonstrated downregulation of folic acid transporters in tissues, especially in the intestine. This could decrease intestinal folate absorption. Livant et al. [282] reported that plasma conjugase activity was reduced in predialysis sera and rose to normal levels after the HD session. The authors suggest that there are one or more circulating heat stable compounds in uremic plasma which may inhibit plasma folate conjugase activity. Moreover, significantly decreased folate receptor 2 (FR2) expression on mononuclear cell membranes has been described in 41

MHD patients compared to 21 healthy controls [283]. This finding is a bit puzzling because the FR2 mRNA was found to be increased and because high plasma Hcy levels, usually present in MHD patients, stimulate FR2 expression. Supplementation with folate decreased the FR2 mRNA but had no effect on the FR2 expression at the cell membrane. The authors conclude that reduced FR2 expression on cell membranes is one of the causes of folate resistance in advanced CKD patients [283].

Marumo et al. [184] reported that in CKD patients who were not receiving folate supplements, serum folate was normal in those with mild-to-moderate CKD and was increased above normal in advanced CKD patients who were not undergoing MHD. In the 1960–80s, reports regarding folate status in MHD patients were contradictory, and both normal and deficient status were described. Marked increases in plasma and red cell folate levels were found in patients receiving folic acid supplements [284]. Folate pools are believed to contain enough quantity to satisfy folate requirements for at least 1 year in normal subjects [152]. Thus it may be necessary to retest MHD patients at least several months, if not more than 1 year, after the interruption of supplementation, to assess the risk of folate depletion. Moreover, most of these studies were conducted before the advent of high-flux/high-efficiency HD that appears to have dramatically increased the risk of folate deficiency in MHD patients. Livant et al. [282] found that of 32 MHD patients treated with high-flux polysulfone dialyzers, 5 individuals had reduced predialysis plasma folate concentrations and 4 had decreased red cell folate levels. The prevalence of folate deficiency might have been greater if 20 of the patients had not been prescribed folate supplements. Leblanc et al. [285] reported the folic acid clearance to be  $134.7 \pm 22.2$  mL/min with high-flux/high-efficiency MHD, with a 26.3% decrease in plasma folate during an individual HD treatment. But whether there is a higher risk of folate depletion with high-flux membranes can be considered controversial, and folate status is not altered when using convective techniques [286,287]. The prevalence of folate deficiency in CPD patients is also controversial [32,158,288,289]. Folate losses into peritoneal dialysate averaged 107  $\mu$ g/day in one study [32].

The influence of ESA therapy on folate status is reported later. Also, according to Biruete et al. [94], sevelamer binds folic acid, and this could impair its intestinal absorption. Soohoo et al. [290] reported that in 9517 incident MHD patients, after adjustment for case-mix, mortality was increased by 18% when serum folates were below 6.2 ng/mL. However, this relationship disappeared after adjustment for nutritional and inflammatory parameters. Folate nutriture in renal transplant patients

is reported to be normal or decreased. The methylenetetrahydrofolate reductase (MTHFR) genotypes, labeled 677 and 1298, were shown to significantly influence plasma folate levels in 733 renal transplant recipients; the 677TT/1298AA group had lower plasma folate levels [291]. In a study concerning the incidence of telomere shortening in chronic dialysis patients and kidney transplant recipients who were followed for 1 year [292], the kidney transplant patients, who had undergone immunosuppression with AZA, had a significantly lower Hcy levels, and similar serum folate levels and telomere length as compared to the chronic dialysis patients. On the other hand, those kidney transplant patients who were treated with mycophenolate mofetil, in comparison to patients who received AZA, presented after 1 year with similar plasma Hcy levels, increased serum folate concentrations and telomere shortening. These findings highlight the complexity of the relationships between these factors [292].

In 75 AKI patients undergoing CRRT, folic acid was found deficient 33% of the patients [160]. In 10 patients receiving treatment with CVVH or hemodiafiltration, the amount of folic acid removed was estimated to be 650 nmol/day, with the folate clearance equal to about 76% of the urea clearance [203]. In 40 patients treated with CVVHD, Datzmann et al. [35] found constant daily losses of folic acid and vitamin B12 during the life of the filter (72 hours). The losses were compensated by the daily supplements of the vitamins.

## Clinical consequences of folate nutriture in advanced chronic kidney disease

### *Folate and anemia*

The advent of the EPO era for chronic dialysis patients increased interest in the body pools and nutritional requirements for vitamins that were directly involved in erythropoiesis, such as vitamin B12 and folates, as well as for iron. There has been concern that in patients beginning EPO treatments, the nutritional needs for these vitamins would increase because of increased utilization during intensive erythropoiesis, and that inadequate body pools of these vitamins (or iron) would reduce the effectiveness of EPO. Mydlik et al. [219] reported a significant decrease of erythrocyte folic acid after 1 year of EPO therapy in 15 MHD patients, suggesting increased utilization with ESA therapy. This was not confirmed by Pollock et al. [293] who did not find differences in folate and vitamin B12 concentrations before versus after 18 months of EPO treatment in 81 MHD and 31 CPD patients. No information was given as to whether the patients in these last two studies received folic acid or vitamin B12 supplements. In a metaanalysis of the treatment of ESA

resistance in chronic dialysis patients, only two studies met the selection criteria for analysis, and no evidence emerged to support vitamin supplementation for patients with ESA resistance [294]. In the KDIGO guidelines on anemia management, no vitamin adjuvants, such as folates, vitamin B12, or vitamin C, are recommended with ESA therapy [268]. The KDOQI guideline on nutrition in CKD does not provide recommendations on this matter [11].

### *Folic acid, Hcy, and methylenetetrahydrofolate reductase gene polymorphisms*

Increased plasma Hcy is a recognized CV risk factor in the general population, and elevation of plasma Hcy in advanced CKD and chronic dialysis patients has been recognized for at least two decades. Hcy-mediated tissue damage has been extensively reviewed [295] and includes increased oxidant stress, impairment of nitric oxide synthesis at the endothelial level, proliferation of smooth muscle cells, and activation of inflammation, all of which participate in the genesis of atherosclerosis. The possibility that reducing plasma Hcy might improve outcomes in advanced CKD, chronic dialysis, and kidney transplant patients has been tantalizing. Hcy is an intermediate compound in the formation of cystathionine from methionine (Fig. 26.6). Three vitamins, B6, B12, and folates, are directly involved in its synthesis and metabolism. The formation of cysteine from methionine requires vitamin B6. PLP is a coenzyme for cystathionine synthase, which transforms methionine to cystathionine, and for cystathionase, which cleaves cystathionine to form cysteine. Vitamin B12 and folate participate in the remethylation of Hcy leading to the reformation of methionine. As suggested in Fig. 26.6, PLP or folate deficiency, which occurs not infrequently in CKD and chronic dialysis patients, could contribute to the rise in plasma Hcy in CKD and chronic dialysis patients. However, CKD patients who have normal levels of folate, cobalamin, and PLP still manifest increased plasma Hcy [296]. In advanced CKD and chronic dialysis patients, plasma Hcy concentrations tend to be about one and one-half to two times the values in healthy controls and correlate inversely with the GFR [297,298]. However, plasma Hcy levels are influenced by the nutritional status and may be low in MHD and CPD patients who have protein–energy wasting (PEW) [299]. Plasma Hcy is also increased in nondialyzed children with advanced CKD and in children undergoing MHD. Arnadottir et al. [300] found that 6 months after renal transplantation, plasma Hcy concentrations had decreased by an average of 14% but were still significantly higher in the renal transplant recipients as compared to a control group matched for renal function.

Plasma Hcy is affected by the dialysis technique. Despite a greater intradialytic decrease in plasma Hcy with high versus low-flux membranes (42% vs 32%), no difference was found in predialysis plasma Hcy levels in patients treated for 3 months with high- as compared to low-flux dialyzer membranes [301]. Pedrini et al. [302] found in a randomized crossover trial that online hemodiafiltration sustainably decreases predialysis Hcy levels when compared to low-flux conventional HD. Vychytil et al. [303] studied peritoneal losses of Hcy in 39 CPD patients. Daily peritoneal Hcy removal ( $38.9 \pm 20.8 \mu\text{mol/day}$ ) was correlated with plasma Hcy, effluent volume, and the D/P creatinine ratio [304]. Free Hcy represented 47.5% and 75.2% of total Hcy in plasma and dialysate, respectively. It was concluded that CPD, like MHD, is not sufficiently effective to normalize plasma Hcy levels.

A number of years ago, two prospective studies described the association between plasma Hcy and CV risk in CKD patients and found elevated plasma Hcy to be a risk factor for endothelial dysfunction and CV disease in CKD patients [305]. Moustapha et al. [306] followed 167 ESRD patients for a 17.4-month period and reported an increased CV morbidity and mortality risk of 1% for each  $\mu\text{mole}$  rise in plasma Hcy. In CPD and MHD patients, Bostom et al. [307] found a relative risk for non-fatal and fatal CV events of 3.0 and 4.4, respectively, when comparing the highest quartile versus the lower three quartiles of plasma Hcy levels during a follow-up of 17.0 months. However, Kalantar-Zadeh et al. [308] found an increased mortality in the lowest quartile of plasma Hcy in 367 MHD patients, even after adjustment for their nutritional and inflammatory states. These authors concluded that Hcy is an independent nutritional marker, and this explained the negative association between plasma values and patient outcomes. The role of Hcy regarding patency of the vascular access is also controversial. Whereas Shemin et al. [309] found a significant relationship between high plasma Hcy levels and vascular access thrombosis in an 18-month prospective study involving 84 HD patients, Bowden et al. [310] found no difference in plasma Hcy levels between 52 MHD patients with more than one episode of vascular access thrombosis and 133 MHD patient controls who did not have vascular access thrombosis during a 16-month prospective study. In a prospective study of 733 renal transplant recipients, Winkelmayer et al. [311] found that the risks of graft loss and patient death were each associated with plasma Hcy levels  $>12 \mu\text{mol/L}$  with hazard ratios after the adjustment of 1.63 and 2.44, respectively.

Many studies have examined the effect of lowering plasma Hcy levels with vitamin therapy in nondialyzed advanced CKD patients, in chronic dialysis patients, and in renal transplant recipients. The findings can be summarized as follows. The usual effect of

folic acid therapy is a 30%–50% decrease in plasma Hcy, but with few patients attaining normal plasma Hcy levels. The magnitude of the Hcy-lowering effect of folic acid is positively related to the pretreatment plasma Hcy values and is negatively associated with the baseline RBC folate concentrations. Most clinical trials in advanced CKD and chronic dialysis patients that used low doses (2.5–5 mg/d) of folic acid to reduce plasma Hcy levels show about the same magnitude of Hcy reduction as in the trials that used larger folic acid doses. Bostom et al. [312] reported a more effective plasma Hcy-lowering effect of a combination of folic acid, vitamin B6, and vitamin B12 in renal transplant recipients than in MHD patients.

Subsequent large-scale, prospective trials addressed the effectiveness of Hcy-lowering therapy on clinical outcomes in CKD patients. The HOST trial included 2056 nondialyzed advanced CKD patients and chronic dialysis patients who were randomized in a double-blind fashion to receive each day either a combination of three vitamins, folic acid, 40 mg; pyridoxine hydrochloride (vitamin B6), 100 mg; and cyanocobalamin (vitamin B12) 2 mg, or placebo [298]. The average duration of follow-up was 3.2 years. Although plasma Hcy fell significantly in the treated group, this group experienced no greater decrease in overall mortality or CV events. In a substudy of this trial, cognition was analyzed as an outcome and also was not improved by the Hcy-lowering therapy [313]. Heinz et al. [314] enrolled 650 MHD patients in a randomized controlled trial that also compared a combination of folic acid, vitamins B6, and B12 to placebo. Again, no difference was found in clinical outcomes (overall and CV mortality and CV events). In a large randomized double-blind prospective trial of 4058 renal transplant patients, the Folic Acid for Vascular Outcome Reduction in Transplantation trial examined the effects of a high daily dose of vitamin supplements (folic acid 5 mg, cyanocobalamin 1 mg, and vitamin B6 50 mg) compared to a lower daily dose of vitamins (no folic acid, vitamin B6, 1.4 mg and cyanocobalamin, 2  $\mu\text{g}$ ) [315]. No difference was found between the two groups with regard to the composite primary endpoint (CV death and CV events). In the Diabetic Intervention with Vitamins to Improve Nephropathy (DIVINE) study, in which 238 nondialyzed diabetic CKD patients were randomized to receive vitamin B12 (1 mg/d), B6 (25 mg/d), and folic acid (2.5 mg/d) supplements or placebo, CKD progression was faster, and the CV events were more frequent in the group receiving the vitamin therapy even though they experienced a significant decrease in plasma Hcy [316]. Metaanalyses that include either nondialysis-dependent CKD or ESKD or with a functioning kidney transplant [317] or only MHD and/or CPD patients [318] have concluded

that the use of vitamin supplements that lower plasma Hcy does not reduce overall or CV mortality.

MTHFR gene polymorphism plays an important role in Hcy and folic acid metabolism and also in the Hcy response to vitamin B supplements [319]. The main variants are at positions 677 (MTHFR 677C > T), 1298 (MTHFR 1298A > C), 1317 (MTHFR 1317T > C), and 1793 (MTHFR 1793G > A). Trovato et al. [320] found in 630 Italian MHD patients a lower frequency of MTHFR 677C > T and MTHFR 1298A > C than in controls who did not have significant renal disease, suggesting that a relationship between this polymorphism may protect against kidney damage. Also, Achour et al. [321] reported that the response of plasma Hcy levels to folic acid and vitamin B12 supplements was related to the presence of the MTHFR 677 phenotype. In a subgroup of 1671 CKD stage 3 hypertensive patients from the China Stroke Primary Prevention Trial (CSPPT), enalapril, 10 mg/d, and folic acid, 0.8 mg/d, reduced CKD progression by 56% and the number of patients with a rapid rate of eGFR decline ( $> 5 \text{ mL/min/1.73 m}^2/\text{year}$ ) by 44% when compared to CKD stage 3 patients receiving enalapril, 10 mg/d, alone. Diabetic CKD 3 patients and MTHFR C677 CC and CT phenotypes demonstrated the greatest degree of slowing of eGFR loss with folate therapy, whereas the decrease in plasma Hcy was greater in the MTHFR C677 TT phenotype. Capelli et al. [295] explained the discrepancies in outcomes among the CSPPT, DIVINE, and the HOST studies on CKD progression by pointing out that the daily folate dose was much different and much lower in the CSPPT study (0.8 mg) than in the DIVINE and HOST studies (2.5 and 40 mg, respectively). Also, there is no folic acid fortification of foods in China, in contrast to the United States (HOST study) and Canada (DIVINE study). So, the usual daily intake of folate is probably substantially less in the Chinese population as compared to the US and Canadian populations.

It is emphasized that the controversy regarding vitamin supplements to lower plasma Hcy in CKD, chronic dialysis, and kidney transplant patients is related to the rather mild increase in plasma Hcy that occurs due to the reduced GFR. Patients with inborn errors of metabolism that cause severe, dangerous hyperhomocysteinemia who have plasma Hcy concentrations that are far greater than 1.5–2.0 times the normal levels that are usually observed in CKD should be given vitamin therapy to lower their plasma Hcy concentrations.

### Folate supplementation in advanced chronic kidney disease, chronic dialysis, and kidney transplant patients

Folic acid supplements appear to be safe for advanced CKD, chronic dialysis, and kidney transplant

patients, even at the range of doses prescribed to reduce plasma Hcy levels. An acute, large load of folic acid may cause AKI in rodents, but this has not been observed in humans [322]. There is the possibility that folate treatment would resolve the hematological disturbances caused by vitamin B12 deficiency, without improving the neurological disorders, or that metabolites of folate might be toxic, possibly by inhibiting the cellular transport of folate. Possible mild side effects of folate, such as nausea, headache, or vivid dreams, have been reported, usually with doses of 5 mg/d or greater [323]. Although many of the more recent studies indicate that plasma and red cell folate levels are usually normal in CKD and chronic dialysis patients, some patients still have low folate concentrations, and high-efficiency/high-flux dialysis may increase the risk of folate deficiency; but this is controversial [282,285]. A low-protein diet usually provides a daily folic acid intake below the RDA. Also, as indicated earlier, there may be endogenous as well as exogenous (i.e., medicinal, Table 26.2) inhibitors of folate in renal failure, and this inhibition might not be reflected in the plasma or red cell folate levels. Moreover, dietary intake of folates may vary substantially, since these patients are often fragile and develop intercurrent illnesses, and body folate pools may be rather quickly depleted. Hence, we recommend a daily folic acid supplement in the order of the RDA (400  $\mu\text{g}$ ) up to 1 mg of folic acid for CKD 3–5, MHD, and CPD patients (Table 26.4). This recommendation differs from the current KDOQI nutrition update in which routine folic acid supplementation of CKD 3–5D patients is not recommended [1]. No folic acid supplement is suggested for the treatment of the modestly increased plasma Hcy levels that commonly occur in chronic kidney failure. This elevation of plasma Hcy has not been shown to have adverse effects; see the earlier discussion on plasma Hcy in CKD.

#### Summary:

- Folate metabolism is abnormal in advanced CKD.
- Dietary folate intake is frequently below the RDA in nondialyzed advanced CKD, MHD, CPD, and kidney transplant patients and chronic dialysis.
- Serum folate levels are often but not always reported to be low in MHD and CPD patients.
- The common prescription of potassium-restricted diets probably contributes to the low folate intake in at least the first three of these patient groups.
- AKI patients receiving CRRT often have low serum folate levels.
- Whether there is a high prevalence of folate deficiency in advanced CKD patients is not clearly established, in

Continued

part, because functional studies to assess for folate deficiency are lacking.

- Whether convective hemodialysis techniques can induce folate deficiency remains controversial.
- Routine folic acid supplementation is not currently recommended for the anemia management of advanced CKD patients receiving erythropoiesis stimulating agents.
- Increased plasma Hcy is very common in advanced CKD and chronic dialysis patients and is associated with adverse clinical outcomes in some but not all studies.
- Folic acid supplements or the combination of folic acid, vitamin B6, and vitamin B12 supplements reduce elevated plasma Hcy to near-normal or normal levels.
- The combination of folic acid, vitamin B6, and vitamin B12 supplements do not improve clinical outcomes in advanced CKD, chronic dialysis, and kidney transplant patients.
- A low dose of folic acid (0.8 mg/d) in combination with the angiotensin converting enzyme inhibitor lisinopril, 10 mg/d, was observed to reduce the rate of GFR decline in nondialyzed Chinese CKD patients.
- Although the KDOQI guidelines on nutrition in CKD do not recommend routine administration of folic acid, we recommend a folic acid supplement of 0.4–1.0 mg/d should be routinely prescribed to advanced CKD, MHD, CPD, and kidney transplant patients and to AKI patients receiving renal replacement therapy.

## Vitamin B12, physiology, biochemistry, and nutritional status in chronic kidney disease patients

### Vitamin B12 physiology and biochemistry

Vitamin B12 (cobalamin, [Table 26.1](#)) is the “extrinsic factor” (i.e., present in food) which, when combined with the “intrinsic factor” (present in gastric juice), results in the absorption of the antipernicious anemia factor which came to be identified as vitamin B12. The vitamin B12 structure consists of a corrin nucleus, a nucleotide, and a cobalt atom. Cobalamins are unstable in light and destroyed by strong oxidation and reduction agents. Cyanocobalamin, the pharmaceutical form of vitamin B12, has been isolated from liver extracts. Coenzyme B12 and methylcobalamin are the metabolically active forms of vitamin B12. All forms of B12 in large doses are equally effective [\[324\]](#). The only natural source of vitamin B12 is bacterial synthesis. Cobalamins are present in animal tissues, mostly liver, meat and seafood, and in lesser amounts in egg yolk and milk. Very small amounts are present in fruits and vegetables. Physiological intestinal absorption follows several steps: free cobalamin is

combined with a salivary peptide binder which then is released in the small intestine by trypsin where it then combines with the intrinsic factor, a glycoprotein molecule of gastric origin. Absorption of the vitamin B12-intrinsic factor complex occurs after binding to a receptor on the brush border of mucosal cells in the ileum. Large pharmacological doses of cobalamins may be absorbed by the small intestine via passive diffusion. Three binding proteins (transcobalamins I, II, and III) participate in cobalamin transport in plasma and in the *in vivo* storage of vitamin B12. Cobalamin stores can constitute up to several milligrams of vitamin B12 and may prevent vitamin B12 deficiency from occurring for several years after intestinal absorption ceases [\[152\]](#) ([Table 26.1](#)). Vitamin B12 is not catabolized and is excreted in bile, with an efficient enterohepatic cycle. Vitamin B12 assessment was formerly performed by microbiologic assays and, more currently, by radioimmunoassay. Vitamin B12 plays a key role in folate metabolism and participates in the demethylation of methyltetrahydrofolate (MTHF) and methylation of Hcy ([Fig. 26.6](#)). This step is essential for the regeneration of THF, which is involved in DNA synthesis by thymidylate synthesis, and for folate delivery to tissues. In the absence of demethylation of MTHF, signs of folate deficiency may occur [\[324\]](#). Furthermore, vitamin B12 is required for myelin synthesis, as demonstrated by the severe neurological disturbances that may occur with pernicious anemia. The exact mechanism of cobalamin action on myelin is unknown. Several medications may interfere with vitamin B12 metabolism or actions. They are summarized in [Table 26.3](#).

### Vitamin B12 intake in chronic kidney disease

In the general population with normal GFR, the upper quintile of vitamin B12 intake has been associated with a lower incidence of CKD [\[14\]](#). The amount of vitamin B12 in diets comprising 40 or 60 g of protein per day is clearly below the RDA ([Table 26.2](#) from Stein et al. [\[15\]](#)). A study from Poland indicates that vitamin B12 intake is below the EAR in almost 50% of nondialyzed advanced CKD and kidney transplant patients, and in 60% of MHD and CPD patients who were not receiving vitamin supplements [\[4\]](#). Martin-Del-Campo et al. [\[18\]](#) reported that a slightly lower proportion of CPD patients, 40%, had a vitamin B12 intake below the DRI. However, in an earlier study, Wang et al. [\[17\]](#) reported an adequate vitamin B12 intake in most CPD patients.

### Nutritional vitamin B12 status in advanced chronic kidney disease and chronic dialysis patients

Plasma vitamin B12 is usually within the normal range in advanced CKD patients. In a study by McMahon et al.

[325] from the Framingham and NHANES cohorts, plasma vitamin B12 was not associated with albuminuria or kidney function. However, higher plasma vitamin B12 levels were associated with reduced kidney function in the presence of high plasma Hcy levels in both cohorts. This was attributed to a possible resistance to the effect of vitamin B12 on plasma Hcy metabolism [325]. Notwithstanding the frequent occurrence of low intakes of vitamin B12 in advanced CKD and chronic dialysis patients (see previous section), serum values of B12 tend to be normal in these individuals (see next section). In MHD patients, even without B12 supplementation and even with years of MHD treatment, serum vitamin B12 is almost always in the normal range [157]. Fehrman-Ekholm et al. [287] did not find decreased serum vitamin B12 levels in hemodiafiltration patients. The normal serum vitamin B12 levels in most advanced CKD and chronic dialysis patients may be due to their inability to excrete vitamin B12 in the urine. In addition, because cobalamin is a large molecule (MW, 1355) and is protein-bound, losses of vitamin B12 into dialysate are low. In CPD patients, no cobalamin was recovered in peritoneal fluid by Boeschoten et al. [32]. Intriguingly, Soohoo et al. [290] reported a higher mortality in patients who were in the three highest quintiles of serum vitamin B12 levels among a cohort of 12,968 incident MHD patients, even after adjustment for comorbidities and nutritional status. This finding has been interpreted as possibly due to a transcobalamin imbalance with increased transcobalamin 1 and 3 maintaining a high plasma vitamin B12 level and decreased transcobalamin 2, which is lower due to inflammation, reducing tissue uptake of vitamin B12.

An inborn error engendering cobalamin deficiency has been described. Cobalamin C deficiency may be caused by mutations of the MMACHC gene (methylmalonic aciduria cblC type with homocystinuria). These mutations lead to a deficit of two active coenzyme derivatives of cobalamin, adenosylcobalamin, and methylcobalamin. This may be responsible for some cases of atypical HUS in children and in young adults [326]. In addition to the microangiopathic lesions found with HUS, typical histological findings include a vacuolated appearance of the glomerular basement membrane and IgM staining of the glomerular capillary wall. This syndrome is dramatically improved by the correction of the cblC defect with parenteral injections of hydroxocobalamin, and, therefore, it is important to consider cblC deficiency in the diagnostic evaluation of atypical-HUS, even when it occurs in adults.

### Vitamin B12 and anemia management in chronic kidney disease

Please refer to the same paragraph in the section on folate.

### Vitamin B12 and Hcy

Please refer to the Hcy discussion in the section on folate.

### Vitamin B12 supplementation in advanced chronic kidney disease, chronic dialysis, kidney transplant, and acute kidney injury patients

Vitamin B12 deficiency is unusual in CKD and chronic dialysis patients, and most authors do not think that vitamin B12 supplements are necessary (Table 26.4). The KDOQI guidelines also do not recommend routine supplements of vitamin B12 [11]. On the other hand, a daily supplement of 2.4 µg of vitamin B12, which is the RDA, is safe and inexpensive and might occasionally help to prevent vitamin B12 deficiency. A vitamin B12 supplement is recommended for AKI-3 patients who are receiving renal replacement therapy (see Chapter 35: Metabolic Management and Nutritional Support in Acute Kidney Injury).

#### Summary:

- Advanced CKD and chronic dialysis patients are usually reported to have normal serum vitamin B12 levels without clinical manifestations of vitamin B12 deficiency, even though studies describe low dietary vitamin B12 intakes in these patients.
- Losses of vitamin B12 during the dialysis procedure are very low because of the relatively large size of cyanocobalamin and the binding of this vitamin to plasma proteins.
- One observational study has reported increased mortality in MHD patients who have high serum vitamin B12 levels; this finding remains to be confirmed.
- Cobalamin C deficiency due to mutation of the MMACHC gene can cause AKI from thrombotic microangiopathy.
- A routine supplement of 2.4 µg of vitamin B12 per day, which is the RDA, is recommended for CKD 1–5D patients and kidney transplant recipients, and for AKI patients receiving renal replacement therapy.

### Niacin (vitamin B3) physiology, biochemistry, and nutritional status in chronic kidney disease patients

#### Niacin physiology and biochemistry

Niacin is the therapeutic agent for pellagra, a condition described initially in maize-eating populations [327]. Niacin is a generic term, including nicotinic acid and nicotinamide (Table 26.1). Active coenzymes from niacin

are the pyridine nucleotides, nicotinamide adenine dinucleotide (NAD), and NAD phosphate (NADP). High amounts of NAD and NADP (the main forms of niacin intake from foods) are present in meat, fish, legumes, coffee, and tea. These compounds are hydrolyzed in the intestine to yield nicotinamide and then nicotinic acid. However, niacin bioavailability may be reduced because of its binding to carbohydrate and peptide macromolecules. Intestinal absorption by passive diffusion is efficient, even for large doses of niacin. Tryptophan is a precursor of niacin, and tryptophan intake alone may be sufficient to provide the RDA (recommended dietary allowance) for nicotinic acid. Niacin is quickly removed from plasma by tissues (mainly by liver and erythrocytes) where it is converted to coenzyme forms. Storage, mostly in the liver, is limited, and signs of pellagra may occur within 50–60 days in humans fed a corn diet deficient in niacin. Excess niacin is methylated in the liver, and the methylated metabolites are excreted in the urine. Niacin status is assessed by measuring nicotinic acid and nicotinamide in blood and red cells, formerly using microbiological assays and currently by chemical measurements or HPLC. The NAD/NADP ratio in red cells, which is decreased in niacin deficiency, may be used as an indicator of niacin depletion in kidney failure patients.

Pyridine nucleotides are involved in at least 200 enzymatic reactions. These may include NAD that is mainly involved in catabolic reactions, such as oxidation of energy substrates, and NADP that is primarily concerned with biosynthetic processes, such as for steroids. These coenzymes are key elements for carbohydrate, fatty acid, and amino acid metabolism. There is a close relationship between the metabolism of niacin and other vitamins. Vitamin B6 and riboflavin are necessary for niacin synthesis from tryptophan. Niacin is necessary for the synthesis of active forms of vitamin B6, riboflavin, and folic acid. Pharmacological doses of nicotinic acid reduce serum total cholesterol, increase the HDL-cholesterol fraction, and decrease serum LDL and VLDL fractions and triglycerides [328]. The mechanisms involved in these different effects on lipids appear to be complex and differ from one fraction to another [329,330]. Dermal flush and skin-related symptoms with niacin therapy have been characterized by the NASTy acronym (niacin-associated skin toxicity) and are an important limitation to treatment with niacin [329]. They relate to the stimulation of G protein-coupled receptor 109A which is distributed widely on immune cells and especially in skin cells. The stimulation of this receptor by an agonist triggers NASTy but does not reproduce the lipid effects of niacin as shown by Olson et al. [330]. Another important property of nicotinamide is the inhibition of the Na/Pi type IIb cotransporter (NaPi-2b) and the type IIa cotransporter (NaPi-2a) in

the intestinal brush border and in the proximal renal tubular epithelial cells of the kidneys, respectively [331]. Large, pharmacological doses of nicotinamide, 500–1500 mg/d given twice daily, by inhibiting active intestinal phosphate transport, can reduce serum phosphorus concentrations in advanced CKD and chronic dialysis patients. Several medicines may interfere with niacin metabolism or actions. They are summarized in Table 26.2.

### Dietary niacin intake in chronic kidney disease

Data regarding niacin intake in CKD are conflictory. Low-protein diets containing 40- to 60-g protein per day may not provide the RDA for niacin (Table 26.3; [15]). However, in 210 stages 4–5 CKD patients, only 1% were reported to have a niacin intake below the recommendation of the National Health and Medical Research Council Nutrient Reference Values for the general Australian population [16]. This contrasts with the findings of Jankowska et al. [4] that about 30% of nondialyzed CKD, chronic dialysis, and kidney transplant patients were deficient in their niacin intake. In this latter study, about 40% of MHD and CPD patients displayed a niacin intake below the EAR. Martin-Del-Campo et al. [18] reported that two-thirds of CPD patients had niacin intakes below the DRI. Bossola et al. [3] found from 3-day diet diaries that the niacin intake was below the RDI in 86% of 128 MHD Italian patients.

### Nutritional niacin status in advanced chronic kidney disease, chronic dialysis, and kidney transplant patients

Because of its rapid metabolic clearance from plasma, losses of niacin in dialysate would be expected to be low. Ramirez et al. [148] did not find differences between pre- and postdialysis red cell niacin concentrations in MHD patients. No data are available concerning niacin losses into peritoneal dialysate. DeBari found in MHD patients low niacin concentrations in leukocytes, but normal niacin content in red cells [332]. Ramirez et al. [148,194] did not find low niacin levels in whole blood or erythrocytes of MHD patients who were not receiving vitamin supplements or in whom such supplements had been stopped for at least 1 year.

### Clinical syndromes involving niacin in acute kidney injury and chronic kidney disease patients

Depletion of NAD is a proposed risk factor for AKI in postoperative patients. This raises the possibility that nicotinamide supplements might be used to prevent AKI in these individuals [333]. In CKD, pellagra

(characterized by diarrhea, dementia, and dermatitis) has never been reported, but niacin deficiency has been suggested as the cause of onycholysis in MHD patients [334]. A post hoc analysis was conducted involving 509 stage 3 CKD patients from the Atherothrombosis Intervention in metabolic syndrome with low HDL/HIGH Triglycerides trial (AIM-HIGH trial) [335]. This trial failed to demonstrate a benefit to adding extended-release niacin to simvastatin with regard to the incidence of adverse CV events. The post hoc analysis indicated that in people with stage 3 CKD, niacin therapy significantly increased serum HDL and reduced serum triglycerides without an effect on CV events but with an increase in the overall mortality (hazard ratio, 1.73). It is not known why overall mortality increased in the people with stage 3 CKD who were given niacin. The trial used a pharmacological dose of extended-release niacin [1500–2000 mg/d that is at around 100 times the RDA (14–16 mg/d, Table 26.4)].

Large doses of niacin have been proposed to treat hyperphosphatemia in CKD, because of the capacity of niacin to inhibit the Na–Pi cotransporter in the intestinal tract [336]. The usual side effects of the molecule, hepatotoxicity, and flush were reduced by changing the formulation from immediate to extended-release and were also less pronounced with niacinamide than with nicotinic acid. A decrease in platelets was encountered with both forms of niacin, nicotinic acid, and nicotinamide, but this is observed inconsistently. The potential advantages of niacin as a phosphate absorption inhibitor are the low cost, the absence of calcium or other cations that are often found in intestinal phosphate binders, the potential benefits on the lipid profile, a potentially lower pill burden, and the fact that the medicine can be taken at a time that is independent of meals [331]. Another post hoc analysis of the AIM-HIGH trial evaluated the effect of niacin therapy on serum phosphate concentrations and other mineral markers in 352 patients with an eGFR less than 60 mL/min/1.73 m<sup>2</sup>. After 3 years of treatment, serum phosphorus had decreased by 0.25 mg/dL in the extended-release niacin group, but no difference was observed regarding serum PTH, FGF-23, calcium, or vitamin D [337]. The effectiveness of nicotinamide as a Pi binder was compared to sevelamer in the NICOREN study [338]. In this open label, randomized study involving 100 MHD patients, serum phosphorus levels were similar after 24 weeks of treatment in the two groups. However, nicotinamide did not reach the significant noninferiority criterion because the number of participating patients was lower than planned and because there was a higher treatment discontinuation rate (60% higher in the nicotinamide group than in the sevelamer group). Also, four patients who were assigned to nicotinamide treatment developed a low

platelet count; none who received sevelamer experienced this adverse event. In a recent metaanalysis involving nine studies and 428 MHD patients, serum phosphorus, PTH, and the CaxPi product were lower in the niacin-treated patients as compared to placebo, and the increased risk of thrombocytopenia with niacin was confirmed [339]. The thrombocytopenia with niacin treatment was mild, and no serious adverse events were reported. Thus clinical trials confirm that niacin effectively decreases serum phosphorus in nondialyzed advanced CKD and chronic dialysis patients. However, the effects of niacin treatment on morbidity, mortality, and quality of life outcomes are still lacking.

### Niacin supplementation in chronic kidney disease, chronic dialysis, kidney transplant, and acute kidney injury patients

A low-protein diet may provide only small amounts of niacin, and some studies have demonstrated a niacin intake below the RDA or DRI in chronic dialysis patients [3,4,18]. We, therefore, recommend the RDA of niacin, 14–16 mg/d, as a supplement for CKD 3–5, chronic dialysis, and kidney transplant patients. AKI patients receiving renal replacement therapy should also receive 14–16 mg/d of niacin. The use of niacin as phosphate-lowering or as a cholesterol-lowering therapy in CKD 3–5, including chronic dialysis patients, is discussed earlier. No specific recommendation has been made for niacin supplementation in the KDOQI nutrition guidelines other than to encourage CKD 1–5D and CKD T1–5 patients to ingest diets providing sufficient amounts of all vitamins and to consider multivitamin supplements for individuals with inadequate vitamin intakes [1] (Table 26.4).

#### Summary:

- In advanced CKD and chronic dialysis patients, niacin intake is often reported to be below the RDA, but blood and red cell levels of niacin generally are normal.
- Clinical syndromes of niacin deficiency (e.g., pellagra) have not been reported in advanced CKD and chronic dialysis patients.
- Niacin can effectively inhibit intestinal phosphate absorption and reduce serum phosphorus levels but may cause flushing, gastrointestinal symptoms, hepatotoxicity, hyperuricemia, and thrombocytopenia.
- More research is needed concerning the effects of niacin on serum lipids (an increase in serum HDL, a lowering of serum triglycerides) in advanced CKD, chronic dialysis, and kidney transplant patients.

Continued

- In stage 3 CKD patients in the AIM-HIGH trial, adding a pharmacological dose of niacin (1500–2000 mg/d) to simvastatin did not change CV outcomes and was associated with increased overall mortality.
- Although niacin deficiency appears to be uncommon in advanced CKD and chronic dialysis patients, since the dietary niacin intake is often below the RDA, a routine supplement of 14–16 mg of niacin per day, which is the RDA, is recommended for CKD 1–5D patients and kidney transplant recipients, and for AKI patients receiving renal replacement therapy.

## **Biotin (vitamin B8) physiology, biochemistry, and nutritional status in chronic kidney disease patients**

### **Biotin physiology and biochemistry**

Biotin (vitamin B8) is a bicyclic compound containing an ureido ring and a tetrahydrothiophene ring (Table 26.1). Although biotin is synthesized by intestinal flora, whether this synthesis is sufficient to satisfy the daily need for biotin in humans is controversial [340]. The main food sources of biotin are liver, egg yolk, soybean, and yeast. Cereals, legumes, and nuts contain moderate amounts of biotin, and fruits and vegetables are poor sources of biotin, except for cauliflower and mushrooms. Biotin absorption occurs mainly in the jejunum and requires the release of biocytin (biotinyl-lysine) from ingested proteins and the action of biotinidase to separate lysine and biotin, which are each absorbed by a diffusive saturable process. Long-term treatment with anticonvulsant medicines, such as carbamazepine and primidone, may interfere with biotin absorption at the intestinal brush border [341]. Other medications may interfere with biotin metabolism or actions (see Table 26.2). Avidin, a glycoprotein that strongly binds to biotin, may also impair intestinal biotin absorption. Free biotin and its metabolites are excreted in the urine. Biotin stores appear to cover biotin needs for about 1 month. A biotin-deficient diet in human volunteers can lead to symptoms of deficiency in 5 weeks [342]. Formerly assessed by microbiological assays, today plasma biotin is commonly measured by ultrahigh performance liquid chromatography–tandem mass spectrometry [343]. Biotin mainly acts as a “CO<sub>2</sub> carrier” being the coenzyme for 5-carboxylases (acetyl-CoA carboxylase, pyruvate carboxylase, propionyl-CoA carboxylase, and B methylcrotonyl-CoA carboxylase). Biotin is covalently bound to the  $\epsilon$ -amino group of a lysine residue of carboxylases. Thus it plays an important role in the metabolism of carbohydrates, fatty acids, and some amino acids. Experimental biotin deficiency was induced in seven healthy human volunteers who

were given a biotin-free diet and an excessive intake of raw egg white (rich in avidin). In 5 weeks the subjects developed mild depression, somnolence, muscle pain, hyperesthesia, anorexia, and later a maculosquamous dermatitis with a greyish pallor and fine desquamation. All symptoms disappeared within 5 days of starting biotin injections [340]. Alopecia is also a common feature of biotin deficiency [342].

### **Dietary biotin intake in chronic kidney disease**

Biotin intake is often below the RDA when daily protein intake is 80 g or less per day (Table 26.3) [15]. However, no data regarding biotin intake in nondialyzed advanced CKD, chronic dialysis, and kidney transplant patients are currently available.

### **Nutritional biotin status in advanced chronic kidney disease and chronic dialysis patients**

Uremic toxins have been shown to impair tubulin polymerization which, under normal conditions, leads to cellular microtubule formation. Biotin counteracts the effects of uremic toxins on tubulin [344]. Several studies did not find biotin deficiency in advanced CKD patients. Biotin concentrations in plasma, leukocytes, and RBC were found to be high in MHD patients [345] and even higher in anuric MHD patients and in long-term MHD patients [152]. Other studies have confirmed high plasma biotin levels in MHD patients [346]. In this last study, 16 MHD patients complaining of skeletal muscle cramps had higher plasma levels of biotin and biotin metabolites than MHD patients without cramps. However, biotin supplementation (1 mg/d) relieved cramps in seven of these patients [346]. Very high biotin plasma levels were reported in one MHD and one CPD patient who received biotin supplements (5 mg/d, and an unknown amount, respectively) [347]. Their plasma biotin levels were 82 nmol/L (normal values, 0.8–3.2 nmol/L). These exceptionally high values have caused erroneous and contradictory measurements for serum thyroid stimulating hormone (TSH), thyroxine (T<sub>4</sub>), and PTH, which were explained by competition between the high biotin plasma levels and the biotinylated antibodies used in the hormone assays.

### **Biotin supplementation in chronic kidney disease, chronic dialysis, and kidney transplant patients**

There is no Institute of Medicine RDA for biotin intake for healthy subjects, but there is an estimation of the dietary biotin need which is referred to as the AI [348]. In the absence of sufficient data to estimate the RDA, the AI is often proposed. The AI is a value based

on the average nutrient intakes or experimentally derived intakes in a group of apparently healthy people who are expected to meet or exceed the amount needed to maintain a state of adequate nutrition in essentially all members of that group. The AI for healthy, normal men and healthy, normal nonlactating women is 30 µg/d (Table 26.4). Whether there is a need for supplemental biotin in CKD 3–5D, kidney transplant or AKI patients is unknown. Biotin deficiency is not reported in CKD 3–5D patients. However, the daily biotin intake with a low-protein diet is below the AI. Again, because CKD 3–5, MHD, and CPD patients not uncommonly have low intakes of many nutrients, it is recommended that they receive a daily biotin supplement equal to the AI, 30 µg/d, for normal men and nonlactating women (Table 26.4). There is no recommendation for biotin in the recent KDOQI nutrition guidelines other than to encourage CKD 1–5D and CKD T1–5 patients to ingest diets providing sufficient amounts of all vitamins and to consider vitamin supplements to prevent or treat micronutrient deficiencies in individuals with persistently inadequate vitamin intakes [1] (Table 26.4).

#### Summary:

- Plasma, RBC, and white cell biotin concentrations are usually reported to be normal in nondialyzed advanced CKD and chronic dialysis patients.
- No data are currently available regarding the dietary biotin intake of CKD or chronic dialysis patients.
- No specific diseases related to increased or decreased body biotin levels have been reported in nondialyzed advanced CKD patients or chronic dialysis patients.
- Biotin supplements can cause very high plasma biotin levels which may interfere with laboratory tests that use biotinylated antibodies; for example, for the measurement of TSH, T4, and PTH.
- The recommended daily intake for biotin for CKD and chronic dialysis patients is the AI for healthy normal men and healthy, normal nonlactating women, which is 30 µg/d.
- Because CKD 3–5, MHD, and CPD patients not uncommonly have low intakes, it is recommended that they routinely receive a daily biotin supplement equal to the AI, 30 µg/d.

### Pantothenic acid (vitamin B5) physiology, biochemistry, and nutritional status in chronic kidney disease patients

#### Pantothenic acid physiology and biochemistry

Pantothenic acid or “chick antidermatitis factor” is formed from the combination of pantoic acid and

β-alanine. Some of its characteristics are given in Table 26.1. Pantothenic acid is used in the formation of CoA and acyl carrier proteins (ACPs), which carry and transfer acetyl and acyl groups, respectively. Pantothenic acid, after passing through several biochemical steps, is converted to CoA, which contains pantothenic acid, adenosine monophosphate, and β-mercaptoethylamine. CoA participates in the synthesis of ACPs. Pantothenic acid is ubiquitous and present in large amounts in many foods, especially liver, kidney, egg yolk, fresh vegetables, royal bee jelly, and tuna and cod ovaries [349]. After CoA hydrolysis, pantothenic acid is liberated and excreted in the urine. Pantothenic acid is currently assessed by radioimmunoassay.

Pantothenic acid is a precursor of CoA, which is necessary for the synthesis of many compounds, including fatty acids, cholesterol, steroid hormones, δ-aminolevulinic acid, and some neurotransmitters and amino acids. CoA is also necessary for energy extraction during the β-oxidation of fatty acids and oxidation of amino acids. Pantothenic acid, as a component of CoA, plays a central role in the acetylation of proteins, microtubules, and histones and in the acylation of proteins (the ACPs) with fatty acids, mainly myristic and palmitic acids. The acetylation and acylation of proteins affect both their structure and activity. In animals, pantothenic acid deficiency results in retarded growth, neuromuscular disorders, abnormalities of skin and hair, and gastrointestinal symptoms. In young men fed a pantothenic-free diet for 9 weeks, their main complaint was fatigue [350]. Several medications may interfere with pantothenic acid metabolism or actions (Table 26.2).

#### Dietary pantothenic acid intake in chronic kidney disease

Dietary pantothenic acid intake is often reported to be below the RDA when protein intake is 80 g or less per day (Table 26.3; [15]). No data regarding dietary pantothenic acid intake in nondialyzed, advanced CKD, chronic dialysis, and kidney transplant patients are currently available.

#### Nutritional status of pantothenic acid in advanced chronic kidney disease, chronic dialysis, and kidney transplant patients

There are few data regarding the nutritional pantothenic acid status in kidney failure patients, and the pantothenic acid data in MHD patients are conflictory. Debari et al. [332] found in 12 nonsupplemented MHD patients that pantothenic acid concentrations in plasma,

leukocytes, and red cells were significantly higher than in normal controls. Lasker et al. [351] reported normal or high concentrations of pantothenic acid in blood of six MHD and three CPD patients who were not receiving vitamin supplements. On the other hand, Mackenzie et al. [352] reported low concentrations of plasma pantothenic acid in six MHD patients who were not receiving pantothenic acid supplements. Surprisingly, the PROGREDIR study, in a cohort of 373 nondialyzed CKD patients, found a positive relationship between pantothenic acid intake and the score for coronary artery calcification (CAC) measured by computed tomography. Other nutrient intakes (calcium, phosphorus, and potassium) were also associated with the CAC score, whereas others (thiamine, riboflavin, pyridoxine, folate, vitamin B12, vitamin K, niacin, zinc, and selenium) were not [353].

### Pantothenic acid supplementation in chronic kidney disease, chronic dialysis, and kidney transplant patients

There are few data on which to base dietary recommendations for supplemental pantothenic acid. Low-protein diets have a reduced content of pantothenic acid. The pantothenic acid clearances with high-flux and/or highly efficient dialysis are unknown. Low concentrations of pantothenic acid have been found in one study in unsupplemented MHD patients [332]. As with biotin, there is no RDA for pantothenic acid in normal individuals, but only an estimation of needs: the AI estimation [348]. Again, because CKD 3–5, MHD, and CPD patients and kidney transplant recipients not uncommonly have low intakes of many nutrients, we suggest that they receive a daily pantothenic acid supplement equal to the AI for pantothenic acid for normal men and normal nonpregnant, nonlactating women, 5 mg/d (Table 26.4). There is no recommendation for pantothenic acid in the recent KDOQI nutrition guidelines other than to encourage CKD 1–5D and CKD T1–5 patients to ingest diets providing sufficient amounts of all vitamins and to consider vitamin supplements to prevent or treat micronutrient deficiencies in individuals with persistently low vitamin intakes [1] (Table 26.4).

#### Summary:

- The nutritional status of pantothenic acid status in advanced CKD and chronic dialysis patients is controversial.
- Dietary pantothenic acid intake of these patients probably is often below the RDA, and normal, elevated, and low blood levels have each been reported in these individuals.

Continued

- No specific syndromes related to low body pantothenic acid have been reported in CKD patients.
- In the PROGREDIR study, pantothenic acid intake was found to be positively related with the CAC score in nondialyzed CKD patients.
- Because CKD 3–5, MHD, and CPD patients and kidney transplant recipients not uncommonly have low intakes, we suggest that they routinely receive a daily pantothenic acid supplement equal to the AI for pantothenic acid for normal men and normal nonpregnant, nonlactating women, 5 mg/d.

### General comments regarding vitamin supplements in kidney disease

In 2001 the KDOQI work group for CPGs for nutrition in chronic renal failure did not address vitamins because of the limited evidence regarding the vitamin needs in kidney failure patients [354]. A few years later a DOPPS report indicated that MHD patients receiving a supplement of vitamins B6, B12, and C, and folates had better nutritional status, as indicated by higher serum albumin levels and nPNA (normalized protein nitrogen appearance), and a 16% decrease in mortality [355]. The reduced mortality persisted after adjustment for nutritional markers. It was not possible to distinguish the specific effects of each vitamin. Vitamin prescription varied substantially across countries, but the impact on mortality did not vary when stratified by geographic regions. The possible explanations for the positive association of improved nutritional status and lower mortality in MHD patients taking vitamin supplements include the plasma Hcy-lowering effects of some of these vitamins, improved patient biochemistry and metabolism due to the vitamin supplements, increased appetite and protein intake with vitamin supplementation, better patient care in chronic dialysis programs where supplements are prescribed, and better socioeconomic status associated with vitamin prescription. However, the prospective trials of Hcy-lowering with vitamin supplements do not support the first hypothesis. Vitamin supplements to prevent deficiency and improve outcomes of renal failure are important issues in these patients, as because morbidity and mortality remain high in this population.

The DOPPS report [355] triggered much interest in water-soluble vitamin supplements for CKD patients. A subsequent small observational study with a 4-year follow-up [356] indicated that water-soluble vitamin supplements have beneficial effects on overall mortality (HR: 0.29; CI, 0.15–0.56). However, since then, no clinical trial or large cohort study has retested the findings from the DOPPS study. The development of new

information in advanced CKD and chronic dialysis patients suggesting greater nutritional requirements for vitamin K and challenging the benefits of vitamin E supplements have raised questions concerning the recommendations for fat-soluble vitamins. Finally, it is not unlikely that many CKD and chronic dialysis patients with PEW or protein–energy malnutrition (PEM) may also be deficient in some vitamins. The extent to which concomitant vitamin deficiencies contribute to the adverse outcomes associated with PEW or PEM is unknown. Whether vitamin supplements would be beneficial to CKD or chronic dialysis patients with PEW or PEM is also unknown and would seem worthy of research. Also, the DOPPS report [355] highlighted the wide disparity of vitamin supplementation in MHD patients across countries, from 3.7% in the United Kingdom to 71.9% of MHD and CPD patients in the United States. The varying availabilities of vitamin supplements specifically designed for renal patients, and the absence of strong clinical evidence for a beneficial effect of vitamin supplements, in the face of the not insubstantial costs of routinely providing regular vitamin supplements to advanced CKD and chronic dialysis patients, may account for these differences.

Since then, several guidelines for the nutritional management of kidney disease patients have been published. Some of these propose guidelines on vitamin supplements (see Table 26.4). The CARI guidelines for nondialyzed CKD patients [357] only suggested guidelines for vitamin supplements because of the absence of level I or II evidence. The CARI guidelines state that CKD patients following a protein-restricted diet should receive supplements of thiamine (B1) (>1 mg/d), riboflavin (B2) (1–2 mg/d), and B6 (1.5–2.0 mg/d of pyridoxine hydrochloride). Steiber and Kopple reviewed the vitamin status and dietary vitamin needs for CKD stages 3–5 patients [358]. The European best practice guidelines [86] recommended for MHD patients 400–800 IU/d of vitamin E based on the SPACE study for the prevention of CV events and the following daily amounts for other vitamins: B1 (1.1–1.2 mg), B2 (1.1–1.3 mg), B6 (10 mg of pyridoxine HCl), C (75–90 mg), folic acid (1 mg), B12 (2.4 µg), niacin (14–16 mg), biotin (30 µg), and pantothenic acid (5 mg). They do not recommend vitamin A supplements but do suggest vitamin K supplements (10 mg/d) for patients undergoing prolonged antibiotic therapy or presenting with bleeding disorders. Tucker et al. [359] commented that the lack of evidence makes it questionable to recommend systematic vitamin supplementation for all MHD patients. However, the authors recognized that in some circumstances, CKD patients will be at increased risk for vitamin deficiencies (e.g., pregnancy, gastrointestinal

bypass, anorexia with poor food intake, vegetarian diets, malabsorption states, and the use of some medications), and they may require individualized prescriptions of vitamin supplements.

The recent KDOQI guidelines for nutrition in CKD (Table 26.4) make the general suggestion that for adults with CKD 1–5D and CKD T1–5, a registered dietitian nutritionist or international equivalent should encourage patients to ingest adequate amounts of vitamins in their diet, should periodically assess their dietary vitamin intake, and consider multivitamin supplementation for individuals with inadequate vitamin intakes for extended periods of time [1]. Supplements are suggested for folic acid, vitamin B12, and/or B-complex (i.e., the eight water-soluble vitamins B1, B2, B3, B5, B6, B8, B9, and B12) for adults with CKD 3–5D and CKD T1–5 not only to correct deficiency or insufficiency based on clinical signs and symptoms (Quality of Evidence and Strength of Recommendation: Level 2B), but also in the case of inadequate dietary intake (Opinion) [1]. Folate with or without B-complex supplements is not advised to prevent Hcy-associated adverse CV events, because there is no evidence that the elevated plasma Hcy typically found in advanced CKD or chronic dialysis patients causes such events (Level 1B) [1]. For vitamin C, and stated as “Opinion,” supplementation to meet the requirements (75 mg/d in women and 90 mg/d in men) is reasonable for CKD 3–5D and kidney transplant patients [1]. For vitamin A and E, no routine supplementation is indicated. When vitamin A or E supplements are prescribed, patients should be monitored for toxicity (Opinion) [1]. CKD 3–5D and post-transplant patients receiving anticoagulant therapy known to inhibit vitamin K activity should not be prescribed vitamin K supplements (Opinion) [1,360].

There is a paucity of definitive evidence regarding the vitamin needs and the causes, prevalence, and optimal treatment of vitamin deficiencies for these patients. As indicated earlier and in Table 26.4, the many sets of recommendations regarding vitamin supplements for patients with kidney disease are often in conflict with each other. Our recommendations for adults with CKD 3–5D and CKD T1–5 are based on our analysis of the available evidence as well as that of other workers in this field. These recommendations also apply to patients with nephrotic range proteinuria unless stated otherwise. For several vitamins, our recommendations differ from the recent KDOQI CPGs on nutrition in CKD [1] because of our perception that CKD, the uremic syndrome, the dialysis process, and medicinal therapy engender many alterations in the physiology and metabolism of vitamins, including in the intake, intestinal absorption, transport and delivery to tissues, degradation, and biochemical activity of the

vitamins. Some compounds that accumulate in kidney failure inhibit the activity of vitamins.

Moreover, we are impressed with the frequency with which advanced CKD and chronic dialysis patients develop acute or chronic intercurrent illnesses or psychological depression which render them anorexic or physically unable to eat a nutritious diet or which further impair the actions of vitamins. As indicated in the previous discussion, the dietary intake of a large number of vitamins have often, although not always, been shown to be below the RDA in CKD 3–5D patients and even in kidney transplant recipients. Moreover, vitamin supplements, if given in appropriate doses, appear to be quite safe. Vitamin supplements for an individual patient are relatively inexpensive. For these reasons, we recommend that CKD 4–5D, kidney transplant 3–5, and often CKD 3 patients should usually be prescribed vitamin supplements. Usually, but not always, the RDA or AI of the vitamin is recommended unless evidence suggests that another dose is more optimal, as indicated earlier, for example, for vitamin B6 (pyridoxine). It is recognized that as research continues in this field, many if not all of the foregoing recommendations may be modified.

## Conclusion

It should be evident from the foregoing discussion that the nutritional requirements for many vitamins are not well defined for CKD 3–5D or CKD T1–5 patients, as well as for AKI patients or individuals with the nephrotic syndrome. Indeed, we still do not know the optimal ways to assess the nutritional status for many vitamins in CKD 3–5D patients, kidney transplant recipients and AKI patients. The blood or plasma concentrations of vitamins may be poor indicators of their functional activities. The example of vitamin K in patients with CKD 3–5D highlights the gap that remains between the currently used, rather crude methods for assessing vitamin status and our need for more precise, sensitive and functional methods. [110]. The effects of kidney failure and uremic toxins on the metabolism and actions of vitamins are largely unknown. The DOPPS cohort study suggesting survival advantages associated with water-soluble vitamin prescription must be confirmed in randomized, prospective clinical trials. However, according to the ClinicalTrials.gov website, no such trials are under way, and we are concerned that they might not be conducted, at least in the foreseeable future. In the last two decades, the hope that vitamin therapy targeting hyperhomocysteinemia in advanced renal failure may improve patient outcomes has vanished. The effects of niacin on intestinal phosphorus uptake, phosphate

balance and the lipid profile must be more extensively investigated. Data concerning vitamin needs and tolerance in CKD patients, such as, for example, for vitamins A and K, have strongly challenged our traditional concepts. New, forthcoming clinical trials may provide much needed information on the safety and role for VKAs for anticoagulation therapy and whether CKD patients may benefit from vitamin K supplements. Thus many unanswered questions remain, and it may therefore be concluded that the field of vitamin metabolism and nutriture in CKD is wide open for more basic and clinical research.

# Trace elements, toxic metals, and metalloids in kidney disease

Sundararaman Swaminathan<sup>1</sup> and Manisha Singh<sup>2</sup>

<sup>1</sup>Division of Nephrology and Hypertension, Mayo Clinic Arizona, Phoenix, AZ, United States <sup>2</sup>Division of Nephrology, Department of Internal Medicine, University of Arkansas for Medical Sciences, Little Rock, AR, United States

## Introduction

Plasma and tissue levels of many trace elements are often altered in patients with acute and chronic kidney diseases (CKDs). Since essential trace elements have important metabolic functions, deficiencies in these elements may lead to either unique syndromes and/or exaggeration of other commonly observed syndromes in patients with kidney disease. Nonessential trace elements and metals may also accumulate in patients with kidney disease and present either with unique clinical syndromes or with other uncertain consequences. In this chapter, we will review the disease processes related to alterations in trace element burden in patients with kidney disease [please see [Chapter 8](#): Catalytic (Labile) Iron in Kidney Disease, and [Chapter 38](#): Nutrition and Anemia in Chronic Kidney Disease, for a more detailed discussion of iron].

current daily-recommended intake is typically less than 100 mg per day. Ultratrace elements are typically defined as those with a daily requirement of less than 1 mg per day.

Trace elements may be differentiated between those with or without established essentiality, and their source is usually from air, water, or diet. Withdrawal or the absence of essential trace elements from the diet will produce functional or structural changes that are usually reversible upon the replacement of the deficient element. Although all of the trace minerals important to human nutrition are elements, they are not all metals (e.g., selenium and iodine). A metalloid is a chemical element with properties in between a metal and a nonmetal. Commonly recognized metalloids include arsenic, antimony, boron, germanium, silicon, and tellurium.

## Trace elements

### Definitions

Trace elements include all naturally occurring elements in the periodic table except the bulk elements and macrominerals. Examples of bulk elements include oxygen, hydrogen, carbon, sulfur, and nitrogen, and their nutritional requirements in humans are in the order of grams per day. Macrominerals include sodium, magnesium, phosphorus, chlorine, potassium, and calcium, and their nutritional requirements usually vary from 1 or 2 g to a fraction of a gram per day [1].

Trace elements are present in the body at less than 0.01% of total body mass, and, if they are essential, their

## Trace element functions

Trace elements serve three broad physiologic functions: (1) oxygen binding and transport; for example, iron (Fe); (2) metabolic catalysis; for example, manganese (Mn), molybdenum (Mo), copper (Cu), zinc (Zn), selenium (Se), and chromium (Cr); and (3) hormonal effects; for example, Se and iodine (I). In addition, the roles of certain micronutrients, especially Fe, Zn, and Cu, are increasingly being recognized for their role in regulating innate immunomodulation and for making a pivotal contribution to the protection against bacterial, mycobacterial, and fungal infections, leading to the concept of “nutritional immunity.” Host cells work through mechanisms of creating a scarcity of these micronutrients as well as flooding the area with them

when needed [2–6]. Located on cellular transmembrane interphases, Toll-like receptors (TLRs) recognize pathogens when activated by their ligands. The activating factors include vitamins and such trace elements as iron, copper, and zinc [7]. Environmental factors, the geographic region, topsoil, water, and dietary habits play a significant role in determining plasma and tissue concentrations of trace elements in the body [8].

### Overview of trace elements in kidney disease

Papers dating back to the 1970s described trace element–related disorders in chronic dialysis patients. Trace element deficiencies, such as zinc and selenium, were recognized in dialysis patients, and oral intake and use of tap water for dialysate were identified as sources of trace element contamination and toxicity [9]. As an example, silicon toxicity was discovered with plasma levels to be almost 100-fold higher in dialysis patients. It was determined that the water used for dialysis preparation was the likely source of toxicities [9]. It also became apparent that the process of dialysis might lead to deficiencies. Aluminum, silicon, copper, zinc, nickel, strontium, and chromium were all shown to have the potential for transfer from dialysate to the patient resulting in toxicity. This led to recommendations for water purification using reverse osmosis technology and for strategies to chelate certain trace elements with deferoxamine, particularly for aluminum toxicity, when indicated [9,10].

Data also emerged regarding the role of trace element toxicity or deficiency as a cause of kidney disease and as a mechanism that may worsen the clinical course of established CKD. As an example, increased levels of phosphorus and copper, and decreased zinc can promote further worsening of CKD and the associated vascular complications through oxidative stress and tissue injury [11].

It is uniquely challenging to assess accurately the accumulation or deficiency of trace elements in CKD patients because of significant changes in the physiologic milieu and the body distribution of some trace elements [12]. Commonly, trace element burden is assessed by serum or plasma measurements; however, plasma trace element levels may not reflect the actual total body stores, because the uremic milieu and the compromised kidney physiology result in preferential excretion or retention of different elements. Further, removal during dialysis, the quality of water used during dialysis, as well as increased urinary loss in kidney transplant patients can all affect measurements [13]. Even brief exposure to renal replacement therapy in the setting of acute kidney disease can impact levels.

In a recent study of patients with acute kidney injury (AKI), Ostermann and colleagues demonstrated that serum levels of zinc, copper, and selenium were lower in more than 30% of patients with AKI, irrespective of whether they were or were not receiving continuous renal replacement therapy (CRRT) [14]. In patients undergoing CRRT, severe deficiencies of selenium and copper have been reported. Thus selenium deficiency observed in critically ill patients may become further worsened by CRRT [15]. Low copper was associated with bradycardia and hypertriglyceridemia. Serum rubidium levels decrease significantly during hemodialysis, because there is little or no protein binding of this element and, hence, it is readily dialyzed. The clinical implications of rubidium removal or low serum rubidium are unclear. There is also a surprising increase in serum levels of chromium, cobalt, molybdenum, and manganese in patients undergoing CRRT [15]. Collectively, these studies demonstrate the importance of close monitoring of trace elements needed in patients undergoing CRRT and the importance of appropriate supplementation.

Important changes in serum trace element levels have also been observed in patients with end-stage renal disease (ESRD), and these changes may be associated with adverse outcomes. In a recent study, Tonelli and colleagues observed that lower serum selenium concentrations were strongly and independently associated with the risk of hospitalization and death in maintenance hemodialysis (MHD) patients [16].

Some caution is required in interpreting these studies, as there may be temporary or associated redistribution of these elements during inflammatory states and associated acute-phase response, making plasma or serum values particularly unreliable indicators of body trace element burden [17]. There are also limitations to the methodology of the laboratory testing. Being present in such small quantities, measurements of these elements need great care during collection and processing of specimens. Furthermore, there is a significant risk of contamination that may even occur from the instruments used for the trace element measurements [18].

We will first focus on essential trace elements and then discuss nonessential trace elements and metals in patients with kidney disease.

### Alterations in essential trace elements in patients with chronic kidney disease

The current literature on alterations in individual essential trace elements in kidney disease will be reviewed and presented in the order of potential importance and available evidence.

## Zinc (Zn)

### Zn distribution

Zn is found in all body tissues with the majority in muscle and bone (85%), followed by the skin and liver (11%), and the rest in other tissues. Body Zn is situated mostly intracellularly. Zn is distributed between the nucleus and the cytoplasm, and in smaller amounts in organelles, vesicles, and the cell membrane. Zinc enters the human body by three known routes: inhalation, absorption through the skin, and by ingestion [19].

Zinc can be obtained from major protein sources, including oysters, poultry, meat, eggs, and whole cereal grains, as well as from fortified foods [20]. The National Institute of Health's Office of Dietary Supplements fact sheet for health professionals provides recommendations and guidelines of the Dietary Reference Intakes developed by the Food and Nutrition Board. This fact sheet provides reference values that can be used for assessing the adequacy of nutrient intakes of normal people [20]. The Recommended Dietary Allowance for zinc in adults is 8 mg per day for normal, nonpregnant women and 11 mg per day for normal men. These recommendations are not directed to the CKD population, and a wide variation is seen in supplementation doses. A metaanalysis reported supplemental elemental zinc doses ranging from 11 to 100 mg for different populations [21]. Zinc is absorbed in the duodenum and proximal jejunum and is transported by apical membrane transporters through enterocytes and circulated to the tissues as protein-bound Zn [22].

### Zn functions

Zinc has an essential role through zinc-containing enzymes and proteins in catalytic, structural, and regulatory functions that affect metabolism, gene expression, and signal transduction [23]. Some of these processes prevent oxidative stress. As noted earlier, Zn plays a significant role in immunity and host defenses. Zn can act as a signaling molecule in signaling cascades, such as in the activation of TLRs [7]. Deficiency of zinc transporter ZIP7 results in impaired B-lymphocyte development and humoral immune deficiency [24]. Zinc transporter, ZIP10, appears to be important for B-cell receptor signaling [25]. Zinc was recently shown to protect against uropathogenic *Escherichia coli* infections [26].

Zinc plays a critical role as a cofactor for many enzymes that regulate a wide variety of cellular activities (e.g., alcohol dehydrogenase, alkaline phosphatase, angiotensin-converting enzyme, and superoxide dismutase). Zinc is an important component of zinc finger proteins that act as transcription factors that allow binding of proteins to deoxyribonucleic acid (DNA) and that control gene expression [27]. In addition, serum zinc-alpha2-glycoprotein, an adipokine associated with

cancer cachexia, is found to be increased in CKD patients. This adipokine appears to predict clinical outcomes independently, including cardiovascular events and mortality, in MHD patients [28].

Zinc is also known for its role in skeletal growth; zinc appears to stimulate osteoblastic bone formation and inhibit osteoclastic bone resorption [29]. Zn is known to play a significant role in wound healing [30].

Bioinformatic processes, including proteomics and genomics, show there are over 3000 unique human zinc proteins, implying that about 10% of the human genome may involve encoding of zinc proteins. There are multiple mechanisms in place to maintain intracellular zinc concentration, highlighting its importance in normal body physiology and also its dynamic regulation within the cell. Disruption in this homeostasis may result in increased oxidative stress and subsequent kidney damage [31].

### Zn measurements

The measurement and interpretation of plasma zinc levels are especially challenging, because plasma levels can be depressed during inflammation and hypoalbuminemia and can be increased postfasting and in catabolic states. Despite this caveat, plasma measurements are preferred over serum due to the lack of erythrocyte contamination. Alternative indirect or secondary markers of the adequacy of body zinc content may include erythrocyte zinc concentrations, activity of such zinc-dependent enzymes as alkaline phosphatase or erythrocyte or monocyte metallothionein, the family of zinc transporters, and gene markers [32].

### Zn toxicity

Ingestion is the primary mode of entry of Zn into the body. Toxic inhalation of Zn can cause pulmonary injury; Zn absorption through skin that may result in systemic effects is rare. Acute intoxication due to exposure to large quantities of Zn is rare. The at-risk populations for chronic toxic Zn exposure are the people working in the metal industries, especially welding. As with some other toxic trace metals, environmental Zn pollution, including Zn contamination of soil, can contribute to rapid worsening of kidney disease in CKD patients [33]. Zinc excess in the body may cause rough hair, diarrhea, microcytic anemia, and hypercholesterolemia. Since zinc competes with copper, manganese, and iron for intestinal absorption, excessive oral zinc intake may lead to copper, manganese, or iron deficiency [34].

### Zn deficiency

Zn deficiency usually is a more common occurrence than Zn excess in people with chronic disease states such as kidney failure, kidney transplantation, anorexia,

malnutrition, and the elderly [23,35]. The mechanisms leading to zinc deficiency include decreased dietary intake, intestinal malabsorption, and losses into dialysate or urine. Zn absorption from the intestinal tract and Zn excretion can be affected by certain medications as well as by phytates in food which may decrease intestinal Zn absorption [36,37].

Marginal zinc intake may be associated with an increased risk of cardiovascular disease in the general population. In animal studies, zinc has been shown to be protective against atherosclerosis by inhibiting the oxidation of low-density lipoprotein cholesterol [38]. Zn deficiency in experimental animals is reported to increase oxidative stress and NF- $\kappa$ B DNA-binding activity and to induce inflammation [39–41]. Zn is essential for insulin synthesis and release and for glucose homeostasis [42]. Data suggest that Zn deficiency may impair insulin secretion and decrease serum leptin levels [43].

Alcoholism, medications such as hydrochlorothiazide, penicillamine, and ethambutol, sickle cell disease, human immunodeficiency virus infection, and liver and kidney disease are associated with zinc deficiency. In the general population, zinc deficiency is manifested by growth retardation, poor wound healing, decreased sexual performance, abnormal hair and nails, loss of taste (hypogeusia), such gastrointestinal (GI) disorders as anorexia, abdominal pain, nausea, and glossitis, and impaired folate and vitamin A absorption. Zinc is also important for neurobehavioral function, and Zn deficiency can result in increased anxiety and depression [44–46].

### Zn in kidney disease

The dietary restrictions that are commonly prescribed for CKD patients, which include a moderate-to-low-protein diet also low in potassium and phosphorus, increase the risk of zinc deficiency, because the foods low in these nutrients are often also low in many other trace elements [47,48]. Zinc deficiency may progressively worsen in advanced CKD and chronic dialysis patients, and studies in experimental animals suggest that zinc deficiency may enhance progression of kidney failure [31].

**Zn and chronic kidney disease** In a study from Korea, lower than recommended mineral intakes, including zinc, were more likely in advanced stages of CKD [49]. A study from Taiwan in type 2 diabetic patients with early CKD (Stages 1–3b) indicated a significant trend toward decreasing serum levels of zinc and iron. This was considered to probably be due to hyperglycemia-induced glycation of basement membrane protein, leading to a loss of charge selectivity with glomerular hyperperfusion and hyperfiltration and urinary trace element losses [50].

Low baseline zinc has been correlated with a more rapid decline in kidney function. Moreover, the mean plasma zinc levels in CKD stage 5 patients were 18% lower than in non-CKD patients. The trend for plasma zinc levels to decrease with loss of glomerular filtration rate was associated with an increase in urinary fractional excretion of zinc. The mechanism for this dysfunctional handling of zinc may be related to progressive tubular injury [51] and its effect on the tubular zinc transporters, ZIP8 (SLC39A8) and ZIP14 (SLC39A14), which can also mediate iron absorption and deposition [52].

Zinc deficiency may lead to the progression of the disease through multiple mechanisms, including increased reactive oxidative damage and kidney hyperfiltration and worsening proteinuria. In addition, zinc deficiency may promote vascular calcification induced by hyperphosphatemia; this process is regulated by the transcription factor NF- $\kappa$ B as has been shown in an animal model and an in vitro study [53]. The findings from these studies also indicate that supplementation may reverse zinc deficiency-induced damages and may represent a possible therapeutic option for CKD patients [31,54].

**Zn and hemodialysis** The mean plasma zinc level, the mean GI absorption, and the mean half-life of zinc are reported to be lower in MHD patients as compared to healthy controls [55]. Dietary zinc intake was normal and did not correlate with plasma zinc, leukocyte zinc, or GI zinc absorption [55]. Lower serum zinc in advanced CKD and chronic dialysis patients may also be related to altered zinc binding to serum proteins. Serum zinc measurements may need to be correlated with serum albumin similar to the way that serum calcium is often adjusted for serum albumin. When serum zinc levels were normalized according to the serum total protein or albumin levels, a significant association was observed between serum zinc and taste impairment in MHD patients [56].

Many MHD patients suffer from zinc deficiency [57–59] (Table 27.1). In one study, 96% of anemic dialysis patients were found to be zinc deficient, based on serum zinc measurements [60]. In patients with serum zinc levels less than 80  $\mu$ /dL, the anemia responded favorably to oral zinc supplementation. In particular, many patients who were receiving erythropoietin (EPO) therapy and diagnosed with refractory anemia had zinc deficiency anemia. Zinc replacement not only corrected the anemia but also substantially lowered the EPO requirements in these patients. Thus zinc deficiency anemia should be considered in chronic dialysis patients who are EPO resistant [60].

**Zn and peritoneal dialysis** Zinc deficiency is a concern for chronic peritoneal dialysis (CPD) patients, especially since they may have higher losses through

TABLE 27.1 Zinc metabolism in kidney disease.

- RDA for zinc for normal men, 11 mg per day, and normal nonpregnant women, 8 mg per day
- Foods with high zinc content: oysters, poultry, meat, eggs, legumes, and whole-grain cereals
- Function: cofactor for many enzymes, zinc finger proteins
- Specific clinical manifestations of deficiency in maintenance dialysis patients: erythropoietin resistance, anxiety, depression, dysgeusia, and hyperammonemia
- Diagnostic laboratory tests: decreased serum zinc levels, low serum alkaline phosphatase (suggestive)

RDA, Recommended dietary allowance.

the peritoneum and stool. In a study of stable CPD patients, the incidence of zinc deficiency was as high as 57.2% [61]. However, Tamura et al. reported the presence of zinc in commercially available PD dialysate, and this zinc was lower in the effluent dialysate, implying significant zinc absorption through the peritoneum during dialysis [62]. Conversely, Mahajan et al. showed that although their patients undergoing continuous ambulatory peritoneal dialysis (CAPD) also had zinc deficiency, they noted a loss of zinc into peritoneal dialysate in their patients. They also reported that episodes of peritonitis were associated with the lowering of serum zinc levels. Data in PD patients are limited compared to HD patients [63].

**Zn and continuous renal replacement therapy** Trace elements can significantly be cleared by CRRT. A retrospective analysis shows that, of the micronutrients measured (thiamin, pyridoxine, ascorbic acid, folate, zinc, and copper) during CRRT in 75 patients, 80% of the 75 were deficient in at least one micronutrient [64]. Prolonged CRRT can cause significant losses of selenium, copper, zinc, and thiamine from serum leading to measurable depletion of these micronutrients [15,65,66].

**Zn and kidney transplantation** Early studies showed that Zn deficiency persists after kidney transplantation in some patients [35]. Serum zinc levels also correlate with selenium levels [67]. Immunosuppressant drugs used in kidney transplant patients, such as mycophenolate mofetil (MMF), may affect serum levels of some trace elements. MMF is known to increase serum copper levels in transplant recipients, increase serum copper and iron in women especially, and decrease selenium level in patients younger than 50 years old. MMF increases Se level in the blood of transplant recipients when used in combination with prednisone [68].

### Zn supplementation

Four short-term randomized control trials (RCTs) examined the effect of oral zinc supplementation on serum lipid levels [69–72]. Argani et al. and Rahimi-Ardabili et al. administered, orally, 100-mg zinc daily to MHD patients for 2 months [69,71]. Argani et al. reported that zinc supplementation did not change serum

cholesterol or triglyceride levels [69]. Rahimi-Ardabili et al. reported that serum cholesterol levels increased significantly in the placebo group but did not change in the treatment group, and that serum cholesterol levels at the end of the intervention period were not different between the two groups [71]. In other studies, Roozbeh et al. [72] and Chevalier et al. [70] supplemented MHD patients with 50-mg zinc daily for 6 weeks and 90 days, respectively. All patients in these two studies had low serum zinc at baseline ( $<80 \mu\text{g/dL}$ ). Total cholesterol, LDL-C, HDL-C, and serum triglyceride levels increased in the zinc-supplemented group, and there was no change in the control group [70,72].

Pakfetrat et al. demonstrated that 50 mg of oral zinc per day for 6 weeks in MHD patients significantly decreased serum homocysteine levels as compared to the MHD patients assigned to the placebo group [73]. A study reported an association between low serum zinc levels and depression in MHD patients [74]. However, there are no well-conducted studies that have examined whether zinc treatment will improve depressive symptoms in MHD patients. Zinc deficiency in MHD patients may also result in hyperammonemia, because ornithine transcarbamylase is a zinc-dependent enzyme; these abnormalities are well corrected with zinc treatment [75].

Two other studies examined the effects of zinc supplements on inflammatory markers; the results were inconclusive. Data on the effects of zinc supplementation on body weight and BMI also gave mixed results [69,76]. In MHD patients with normal or low bone turnover, a single-center study from Japan found a positive effect of zinc supplements on bone formation independent of parathyroid hormone (PTH) and vitamin D [77].

Several clinical studies examined the effect of zinc supplementation on serum zinc levels in MHD patients [34,69–72,76,78]. The dose of the zinc supplements ranged from 11 to 110 mg per day, and the study duration ranged from 5 weeks to 6 months. A pooled analysis of these studies showed a mean increase in serum zinc of  $30.97 \mu\text{g/dL}$  (95% confidence intervals, 17.45, 44.59) after supplementation as compared to the control group, but there was high heterogeneity. There is evidence that low-dose zinc supplements do not correct low-zinc status in the MHD population [78]. However,

it is not firmly established whether zinc supplementation affects any clinical outcomes in CKD patients.

A small study from Japan reported a decrease in left ventricular end-diastolic size after 3 months of concomitant zinc and selenium supplements in 18 MHD patients. The MHD patients also exhibited an increase in natural killer-cell activity—a vital host response to infected cells. Investigators used a formula that contained 50 µg of Se and 12 mg of Zn, along with other nutrients, including protein and 12 vitamins and 10 minerals, once daily for 3 months [79]. It should be emphasized that the long-term benefits or toxicity of zinc supplements, and the doses of zinc supplements at which these effects might occur are unknown. Chronic zinc supplementation can induce copper deficiency [80].

Copper (Cu)

Cu distribution

Copper (Table 27.2) exists in the body in two oxidative states, as the cuprous (Cu<sup>+</sup>) and cupric (Cu<sup>2+</sup>) ions. The normal adult human body contains about 50–120 mg of copper, with the highest content in the liver (10–35 µg/g of dry weight). Copper is primarily excreted via bile (2 mg/day), and normally about 10–50 µg of copper are excreted daily in the urine. Ceruloplasmin is the major copper-binding protein in the blood and in plasma; 60%–90% of the copper in plasma is bound to ceruloplasmin, and the remainder is loosely bound to albumin. The normal plasma copper level is about 0.75–1.45 µg/mL, and plasma ceruloplasmin levels are 190–510 µg/mL. In the Western diet, 60% of dietary copper comes from vegetable sources (grains, nuts, and chocolates), and 20% is derived from meat, fish (particularly shellfish), and poultry [81]. Recommended daily intake for copper is about 340 µg for children to about 900 µg for adults. Copper is absorbed in proximal small intestine and stomach. Acidic environment of stomach facilitates absorption by dissociation of copper from complexed macromolecules. Dietary absorption of copper can be impaired by iron, zinc, or ascorbic acid.

Cu functions

Copper serves as a cofactor for many enzymes, known as cuproenzymes. Copper is essential for the

function of several well-known enzymes, including superoxide dismutase [Cu/Zn superoxide dismutase (SOD) is an antioxidant], amine oxidase (monoamine oxidase), lysyl oxidase (involved in collagen synthesis), tyrosine hydroxylase, dopamine beta-hydroxylase (involved in skin pigmentation), factor V (for coagulation), and cytochrome *c* oxidase. Cu/Zn SOD has two atoms of copper per molecule and is present at high levels in the brain and kidney, among other tissues. Copper plays an additional important function in iron metabolism, which is mediated through ceruloplasmin or ferroxidase. Cu has a pivotal role in immunomodulation combating infections [5]. Innate immune cells utilize Cu through different pathways to achieve an effective interface to protect the host. These processes include the regulation of Toll-like receptors and the compartmentalization or sequestration of infected cells [4,6].

Cu measurements

For clinical purposes, copper has been measured using some direct measurements like serum and plasma-free Cu levels, and also through various correlations such as ceruloplasmin concentrations, erythrocyte superoxide dismutase activity, and platelet Cu concentration. Historically, plasma Cu levels were estimated by a calculation that assessed the copper index or nonceruloplasmin-bound copper. However, this process was not very accurate, and currently most laboratories directly measure copper concentrations.

Copper measurements are helpful in states of clear deficiency but are not helpful if there is a suspicion of moderate reduction in copper intake or moderate deficiency. In pregnancy and such diseases as rheumatoid arthritis, leukemia, lymphoma, or primary biliary cirrhosis, plasma ceruloplasmin levels can increase, thus making copper measurements less accurate indicators of deficiency or excess in individuals with these conditions. Platelet copper concentrations and cytochrome *c* oxidase activity may be more sensitive indicators of marginal dietary copper intake or copper deficiency [32]. Cu is commonly measured in serum or plasma by quantitative inductively coupled plasma-mass spectrometry in reference labs [82].

TABLE 27.2 Copper metabolism in kidney disease.

• RDA for copper for normal men and normal nonpregnant women: 900 µg per day
• Major dietary sources: nuts, chocolates, meat, and shellfish
• Function: cuproenzymes, collagen synthesis, and iron metabolism
• Specific clinical manifestations of deficiency in maintenance dialysis patients: erythropoietin resistance, anemia, neutropenia, and neurodegenerative illness
• Risk factors for deficiency: bariatric surgery, zinc supplementation, and parenteral nutrition
• Laboratory tests to diagnose copper deficiency: low serum copper and ceruloplasmin levels; serum ferritin may be high
• Copper accumulation: historic, in patients dialyzed with cuprophane membrane; link to dialysis-related amyloidosis

RDA, Recommended dietary allowance.

## Cu toxicity

Copper toxicity, though rare, does occur. The route of intoxication can vary—most commonly by oral intake through suicidal intent, indigenous medications, and practices such as boiling milk in copper vessels, herbal medications, alternative medical practices, or supplementation [83]. An Italian study reported increased intake of copper, as compared to other trace elements, in a cohort of MHD patients [84]. Copper toxicity can also happen through an intravenous administration [85], transcutaneous absorption via wounds or chemical burns [86], intrauterine (e.g., for abortion), and also by the intrarectal route, as described in an unusual case report where the patient used it to treat infertility [87].

Copper sulfate toxicity can present with GI symptoms, including bleeding, hepatotoxicity, kidney failure, and multiorgan failure. There may be a role of serum alanine aminotransferase and aspartate aminotransferase measurements for identifying patients at higher risk of mortality (sensitivities of 100% and 85.7%, and specificities of 73.1% and 69.2%, respectively, for peak serum alanine aminotransferase levels greater than 55 U/L, and peak serum aspartate aminotransferase levels greater than 234 U/L) [88].

## Cu deficiency

Several minerals influence copper absorption from the GI tract. Dietary zinc, in particular, can decrease copper absorption through the stimulating effects of zinc on metallothionein synthesis and the subsequent binding of copper by metallothionein. Excess dietary iron also can decrease copper absorption. In patients undergoing CPD, loss of ceruloplasmin-bound copper into the dialysate may lead to copper deficiency. People who have proteinuric kidney diseases may have increased urinary copper losses that may also contribute to copper deficiency. Thus previous bariatric surgery, malabsorption, zinc supplements, proteinuria, and CPD serve as risk factors for copper deficiency.

Copper deficiency in the general population is characterized by fragile, abnormally formed hair, depigmentation of the skin, myeloneuropathy, ataxia, edema, osteoporosis, and hematologic changes (microcytic anemia and neutropenia) (Table 27.2). Neurologic manifestations due to copper deficiency may be precipitated in patients who have undergone bariatric surgery [80] and those who are receiving dietary zinc supplements [89].

## Cu and kidney disease

**Cu and acute kidney injury** Excess copper intake can cause a syndrome of hemolysis and AKI [90]. The intravascular hemolysis is associated with methemoglobinemia. Acute copper toxicity may cause acute tubular necrosis; tubulointerstitial nephritis and rhabdomyolysis [91].

**Cu and dialysis treatment** Copper accumulation has been described historically in patients who received hemodialysis with a cuprophane membrane, which is a cellulose membrane prepared by the cuprammonium method that contains small amounts of copper [92,93]. Studies have shown a potential contributory role for copper in the genesis of  $\beta$ 2-microglobulin amyloidosis (also known as dialysis-induced amyloidosis) [94].

Klein et al. had reported cases of hemodialysis-induced severe copper poisoning presenting with hemolytic anemia due to the contamination of dialysate by oxidative release by heat and acid of copper in the dialysis heating coils [95]. Over the following years, equipment manufacturers eliminated copper tubing from dialysis machines, and stringent monitoring of the pH and conductivity became the standard of care. However, this route of copper toxicity is still a concern. Modern plumbing systems commonly incorporate backflow prevention devices that are made from brass. The ultrapure water needed for preparing incenter dialysate is highly corrosive and carries the potential to leach copper and zinc from these devices. The Association for the Advancement of Medical Instrumentation, a national organization that develops standards and promotes safe, effective use of medical instrumentation and related technologies, continues to work with the International Association of Plumbing and Mechanical officials to address these concerns. An amendment to the existing codes was proposed to designate the dialysis water system, including all of its plumbing components, as a medical device. The amendment also proposed that backflow prevention devices not be needed at the inlet of each dialysis machine. However, there is certainly a requirement for backflow prevention at the inlet to the dialysis water system [95–97]. Copper toxicity is usually treated with chelation (e.g., D-penicillamine or trientine) or zinc supplementation.

Copper deficiency may be present and remain undiagnosed in chronic dialysis patients [47,98–101]. Symptoms of copper deficiency described in maintenance dialysis patients include neutropenia [102], EPO-resistant anemia [103], bicytopenia (the combination of anemia and neutropenia) [104], and neurodegeneration (cerebellar, spinal cord, and peripheral nerve disorders) [80].

An MHD patient with copper deficiency was presented with ataxia and paresthesias and had magnetic resonance (MR) imaging that displayed an image indistinguishable from subacute combined degeneration of the spinal cord. The copper deficiency was considered to be secondary to chronic zinc supplementation [105].

Ceruloplasmin-related indexes were reported to show moderate Cu deficiency in CPD patients. However, this was not confirmed by erythrocyte SOD activity or mononuclear cell copper measurements [99].

Significant losses of copper and selenium into the effluent dialysate can occur during CRRT. This is

especially likely to occur in patients who receive prolonged CRRT for AKI. A patient who received CRRT for 180 days developed copper deficiency with the life-threatening symptoms of bradycardia and hypertriglyceridemia [66].

The treatment of copper deficiency usually consists of oral copper supplementation. In patients receiving total parenteral nutrition (TPN), intravenous copper replacement may be necessary, particularly if the TPN is given for an extended period.

Changes in the metabolism and serum levels of copper and zinc occur simultaneously in kidney transplant patients. The literature has been covered previously in the “Zn and kidney transplantation” section.

### **Manganese**

The total amount of manganese (Mn) in the adult human body is about 12–20 mg. Of the organs, bone and the kidney have some of the highest concentrations of manganese. Within the cell, it is concentrated in the mitochondria and the nucleus. Manganese is a key component of metalloenzymes. Manganese is important in the formation of cartilage, in glucose metabolism, and in the activities of enzymes, such as arginase and manganese superoxide dismutase (which has antioxidant function). Dietary sources of manganese include whole-grain cereals, fruits, and vegetables. After intake, Mn is sequestered to body tissues, thus making plasma level measurements unreliable for assessing exposures or toxicity. Measurements of Mn in red blood cells or whole blood give a more reliable estimate of the adequacy of the body Mn content rather than plasma levels; thus most studies use whole blood Mn levels [106].

In CKD patients, blood Mn concentrations correlate positively with serum hemoglobin levels. Higher blood Mn levels are independently associated with a decreased risk of anemia in CKD patients [107]. There may be an association between worsening CKD and blood Mn levels [108,109].

Low blood Mn levels were associated with an increased prevalence of diabetes and kidney disease in a large prospective Korean study, suggesting that blood Mn deficiency might be involved in the pathophysiological processes of diabetes and diabetic nephropathy [108]. Some data indicate that higher blood pressures may be correlated with higher Mn levels [110]. Blood manganese levels are often low in MHD patients [58]. Serum manganese concentrations correlate with the protein–energy status in MHD patients [111]. A study showed an association between low serum manganese levels and increased carotid atherosclerosis in MHD patients [112]. In some MHD patients, serum manganese levels are increased and also exhibit deposition of manganese in the cerebral basal ganglia, which are visualized as hyperintense

signals on T1-weighted MR images. These patients may present with extrapyramidal syndromes, Parkinsonism, myoclonus, and vestibular auditory syndromes [113].

### **Selenium**

Selenium (Se) is an essential trace element that is important for controlling oxidative stress, by modulating glutathione peroxidase (GPX) activity, which is an important defense against iron-mediated lipid peroxidation and ferroptosis (a programmed cell death that is dependent on iron and is characterized by the accumulation of lipid peroxides), immune function, and thyroid hormone synthesis [114]. In the kidney, selenium appears essential for the function of GPX4, a critical enzyme that protects the kidney from ferroptosis and AKI [115]. Selenium deficiency has been found to be associated with bone disease (endemic osteochondropathy or Kashin–Beck disease) and cancer and may increase the risk of cardiovascular diseases [116]. Keshan disease is an endemic cardiomyopathy due to selenium deficiency that is seen in parts of China where the soil is deficient in selenium [116].

Se supplementation improved cellular GPX activity in patients with different stages of CKD [117,118]. Serum selenium levels are often decreased in MHD patients [47,114], and serum selenium levels correlate with the patient’s protein–energy status [114]. Correction of selenium deficiency results in increased GPX activity with a potential reduction in oxidative stress [119] and is also shown to reduce DNA damage [120]. Omrani et al. showed that selenium supplementation does not have any significant effect on thyroid function tests, acute phase reactants, or the lipid profile in MHD patients [118].

In a population-based cohort study of 1040 MHD patients, the quartiles of serum selenium levels were inversely associated with death risk. Particularly notable was the increase in death associated with infectious complications in patients who had the lowest serum selenium concentrations [121]. Decreased serum selenium levels in MHD patients may be associated with increased cardiovascular risk [122]. In addition, lower serum concentrations of selenium in MHD patients are independently associated with the risks of hospitalization and death [16].

Selenium may also have a protective effect against vascular calcification [122]. The content of food selenium can depend on soil selenium levels. However, a study that compared MHD patients living in areas of Brazil with high soil selenium content (north Brazil, Amazon soil) versus low soil selenium (southeast Brazil) found that, independent of region, MHD patients have low serum selenium levels [123].

Supplementation with Brazil nuts (the richest known food source of selenium) corrects selenium deficiency in MHD patients [124]. Whether ingesting Brazil nuts will

reduce oxidative stress and inflammation in MHD patients was studied in a prospective, uncontrolled 3-month clinical trial. The trial was conducted to determine whether the beneficial effects for MHD patients of taking one Brazil nut per day for 3 months would be sustained 12 months after cessation of the Brazil nut intake. Total 29 MHD patients (58.6% men,  $51.0 \pm 3.3$  years) in Rio de Janeiro, Brazil, were evaluated 12 months after the supplement study had ended. Plasma levels of such antioxidant substances as selenium, GPX, 8-isoprostane, 8-hydroxy-2-deoxyguanosine (8-OHdG), and the cytokines, tumor necrosis factor alpha, and interleukin-6 were measured before, after 3 months of supplementation, and after 12 months. After 3 months of supplements, the plasma cytokine, 8-OHdG, and 8-isoprostane plasma levels had decreased, and plasma activity of GPX and selenium had increased. These changes were statistically significant. At 12 months the plasma values of 8-isoprostane, 8-OHdG, and cytokines had significantly increased and the plasma activity of GPX and selenium was significantly decreased. These data indicate that these biomarkers of oxidative stress and inflammation biomarkers 12 months after cessation of the Brazil nut treatment were increased as compared to the baseline as well as compared to 3-month levels. Hence, it would seem that to attain a sustained beneficial effect, it is necessary to motivate patients to continue to take the Brazil nuts [124].

Selenium toxicity or selenosis is rare and is manifested by brittle hair, breath with a garlic-like odor, GI symptoms such as nausea, vomiting, diarrhea and, rarely, acute tubular necrosis [125].

### **Boron**

Boron, the fifth element in the periodic table, is ubiquitous in nature. Boron in humans is mostly present in the bone and seems essential for the structure of bone [126,127]. Boron is beneficial particularly to bone and mineral metabolism in the setting of vitamin D deficiency [128,129]. This may be particularly relevant to CKD and chronic dialysis patients who commonly exhibit significant vitamin D deficiency. Exposure to boron has been implicated as a cause of AKI as well as a potential cause of CKD in Southeast Asia [130]. Hemodialysis treatments substantially decrease serum boron levels [131]. The consequences of boron deficiency are unknown.

### **Chromium**

Chromium (Cr) is an essential element. Its primary role appears to be the enhancement of insulin sensitivity at the muscle cell level, which is mediated through a binding protein known as chromodulin. Chromium deficiency, thus, can result in insulin resistance. The recommended daily intake is about 30–35  $\mu\text{g}$  per day.

Rich dietary sources of chromium include egg yolks, meat, and whole grains [132].

The effects of chromium deficiency on patients with kidney disease still need to be investigated. Chromium toxicity, on the other hand, has been implicated as a cause of kidney diseases, including acute tubular necrosis and chronic interstitial nephritis, and as a cause of proteinuria. Chromium toxicity is considered an occupational hazard in chromium workers (platers and welders). The diagnosis of chromium toxicity is helped by a high index of suspicion. A history of occupational exposure may offer a clue to diagnosis. With hemodialysis and supportive care, it is a potentially salvageable condition [133].

A 21-year-old man, a worker in a mobile phone shop, was admitted with rhabdomyolysis, kidney failure, and pulmonary edema requiring mechanical ventilation and hemodialysis. After extensive workup and ruling out of other causes, heavy metal poisoning was considered. Investigations during the course of the hospital stay revealed inadvertent chromium poisoning. With repeated hemodialysis, his condition improved, and he was discharged home in a stable condition [133]. A study from Taiwan reported that the decline in kidney function due to lead and cadmium was enhanced with coexposure to chromium [134]. Cr toxicity has been suggested as a possible cause of CKD of unknown origin [135].

Measurement of Cr, like other metal ions, needs a consideration of the valency, as there is a difference in effects of different valencies. Cr(VI) ion, known to be carcinogenic and cytotoxic, can easily be transported across cells and is associated with oxidative stress due to the reduction to Cr(III) in vivo, whereas the Cr(III) ion may be beneficial [136]. Serum Cr was found to be higher than in CPD patients than MHD patients possibly due to the absorption of chromium from peritoneal dialysate [137], although a decrease in serum chromium levels using typical peritoneal dialysate solutions have also been reported [138].

### **Fluoride**

Fluoride is an essential trace element that is important for dental and bone health. Fluoride is one of the most powerful known oxidants. Serum and bone fluoride content are generally increased in patients with reduced kidney function [139]. In a recent study, fluoride accumulation was thought to contribute to the pathogenesis of endemic CKD of unknown etiology (CKDu) [140]. Toxic effects of fluoride have been described in osteoblasts [141] in chronic dialysis patients; however, no causal relationship with osteomalacia and high levels of deposition of fluoride in bone of MHD patients could be established [142]. Acute fluoride intoxication in MHD patients due to the contamination of dialysate water has been reported.

These patients manifested severe pruritus and, in some patients, fatal ventricular fibrillation [143]. The mechanisms of these fatal toxic effects include the induction of profound hypocalcemia, inhibition of  $\text{Na}^+ - \text{K}^+ - \text{ATPase}$ , and development of an explosive hyperkalemia [144].

### **Cobalt**

Cobalt is an essential component of vitamin  $\text{B}_{12}$ . In the past, cobalt chloride was used to treat the anemia of CKD [145]. Cobalt induces erythropoiesis, acting as an inducer of hypoxia-inducible factor (HIF) [146]. Because of its side effects, including cardiomyopathy and thyroid dysfunction, its use was discontinued [147]. There is a positive correlation between serum cobalt levels and atherosclerosis in MHD patients [112]. More rigorous studies are needed to examine the potential benefits and hazards of cobalt intake for chronic dialysis patients.

### **Silicon**

Silicon has been thought to be an essential element involved in bone mineralization [148]. There is a unique affinity of silicon to aluminum, and it has been suggested that silicon deficiency could be a predisposing factor for aluminum toxicity [149]. Silicon is excreted primarily in the urine, and silicon may accumulate in chronic dialysis patients [150,151]. Silicon is found to accumulate in a normal aging population over 60 years, still higher levels of silicon were detected in the liver, spleen, lungs, skin, bone, and vessels of chronic dialysis patients who are at higher risk of toxicity. In addition, MHD patients develop higher plasma levels than non-dialyzed uremic patients [152]. There is a reported association between silicon accumulation and perforating folliculitis [153] and liver and neurologic dysfunction [154,155]. Additional consequences or benefits of silicon deficiency or accumulation have not been well investigated in chronic dialysis patients.

## **Alterations in nonessential trace elements, metals, and metalloids in patients with kidney disease**

### **Aluminum**

Aluminum accumulation was historically described in MHD patients as a consequence of using hemodialysate prepared from tap water that was contaminated with aluminum sulfate added as a purifying agent [156,157]. Aluminum is added to the water in the form of alum to remove suspended colloidal matter by a process called flocculation. Tap water may also be derived from sources such as streams or rivers that may naturally contain higher levels of aluminum.

Other potential sources of aluminum include dietary sources, aluminum-containing phosphate binders, and aluminum-containing antacids [158]. In addition, aluminum can be a contaminant or impurity in various other dialysis-associated medications, especially injectable iron, insulin, and EPO [159].

Aluminum accumulates in a variety of organs in chronic dialysis patients, including the lungs, skin, brain, and bone [160–162]. It is present along the mineralizing front of bone. The deposition of aluminum in bone may be underdiagnosed in MHD patients who may be asymptomatic even when a significant amount of aluminum deposition has occurred [163].

Diabetes mellitus and citrate intake are risk factors for increased aluminum accumulation [164,165]. Dietary citrate makes a complex with aluminum, thereby facilitating its intestinal absorption. Citrate also promotes aluminum absorption by enhancing the solubility of this mineral over a wider range of pH values. With respect to these effects of citrate, a careful assessment may be needed with the recent introduction of citrate-based binders, although a RCT did not show a significant difference in serum aluminum levels between the binder-treated group and the non-treated controls [166].

Aluminum accumulation has been shown to cause anemia [167], low-turnover bone disease [168], and dialysis dementia [169]. Studies have also implicated aluminum accumulation with left ventricular hypertrophy [170,171]. With improvements in water treatment, reduction in the use of aluminum-containing phosphate binders, and the not infrequent monitoring of plasma aluminum levels, aluminum-related diseases have largely disappeared in chronic dialysis patients. Of interest, studies have observed tissue aluminum accumulation in patients with nephrogenic systemic fibrosis (NSF) and calciphylaxis [172]. The sources and consequences of aluminum accumulation in these disease processes are unknown. Aluminum toxicity is treated by identifying and removing sources of aluminum, prudent use of deferoxamine chelation and, in high-dose toxicity, treatment with high-flux intensive hemodialysis.

### **Antimony**

Antimony (Sb) is a nonessential metalloid. Sources of antimony exposure include both occupational (welding and smelting) and therapeutic sources [173]. Exposure to antimony can also occur from environmental waste, especially in areas where electronic waste recycling is conducted. Antimony is widely used in its pentavalent form to treat visceral leishmaniasis and as pentamidine to treat pneumocystis infection. Trivalent antimony is known to degrade heme and is a potent inducer of heme oxygenase [174].

Antimony therapy can induce nephrotoxicity, causing both AKI and renal tubular acidosis [173]. No data are available on the blood and tissue antimony levels of patients with CKD.

### **Arsenic**

Arsenic (As) is nephrotoxic, particularly after acute exposure to arsine [175–177]. Patients exposed to arsenic develop hemolysis, acute kidney failure with cortical necrosis, CKD, and peripheral neuropathy [177–179]. The source of arsenic appears to be more diet related in the dialysis population. Arsenic accumulates in MHD patients more than in peritoneal dialysis patients, likely due to the better clearance by CAPD [180].

Arsenic accumulates in the serum and tissues of patients with renal insufficiency [181,182]. A study of human kidney epithelial cells indicates that long-term exposure to arsenic, even at low levels, can increase the risk of kidney fibrosis; this is mediated in part by DNA methylation [183]. This raises the possibility that some of the toxic changes can be reversed by epigenetic therapeutics [183]. Sources of arsenic include contaminated water and food, such as tilapia fish. Cutaneous manifestations of chronic arsenic exposure are generalized hyperpigmentation, palmoplantar hyperkeratosis, and Mees' lines in the nails [184]. Arsenic induces oxidative stress, and chronic arsenic exposure may be a causal factor for atherosclerosis, progression of kidney disease, and increased risk of cancer [185–187].

### **Cadmium**

Cadmium (Cd) levels are increased in the blood and bone of MHD patients [13,47]. Major environmental sources of cadmium include the diet and smoking [188]. Cadmium toxicity has been associated with increased risk of cancers, kidney disease, and osteoporosis [189]. A study from Japan identified cadmium toxicity as causing itai-itai disease with characteristic clinical features, including renal tubular dysfunction, osteomalacia, and anemia with low EPO levels [190]. Animal studies show that the mechanism of anemia development may be through hemolysis, iron deficiency, and changes in iron metabolism with insufficient EPO production [191]. A study from Sri Lanka has suggested a link between environmental cadmium exposure and CKD of unknown etiology [192], although other studies have not confirmed these findings [193]. Preclinical research suggests that cadmium may induce diabetic nephropathy [194], and clinical studies have suggested a pathogenic link between cadmium and worsening diabetic nephropathy [195]. Cadmium is thought to mediate these pathogenic effects by worsening both glycemic control and direct nephrotoxicity. Cadmium may also cause vascular toxicity, since there is a significant and direct association

between serum cadmium levels and endothelial dysfunction, as measured by decreased flow-mediated dilatation, in MHD patients [196].

An association has been reported between elevated blood cadmium levels and increased 18-month all-cause mortality in diabetic MHD patients [197]. These findings are consistent with the possibility that cadmium may exert systemic toxicity through its nephrotoxic (tubular toxicity), proinflammatory, and vasculotoxic/proatherosclerotic effects [112,189]. In fact, a study suggests an association between environmental cadmium exposure and malnutrition, inflammation, and protein-energy wasting [malnutrition–inflammation–cachexia (MIA) syndrome] in MHD patients [198,199]. Elevated serum cadmium levels ( $>1.38\text{ }\mu\text{g/L}$ ) were associated with a 10-fold increased risk of inflammation [198].

In addition, cadmium exposure has been associated with a higher incidence of hypertension, especially in women who are nonsmokers [200]. It is possible that the cause of the hypertension may be due to an alteration in the tubular expression of cytochrome P450 enzymes that catalyze the hydroxylation of arachidonic acid. This reaction produces eicosanoid 20-hydroxyeicosatetraenoic acid (20-HETE), which is involved in vascular function, and salt excretion by the kidney, and may thereby regulate blood pressure. The 20-HETE can be measured in the urine [199].

Urinary cadmium excretion may be used to assess total body cadmium content. Interpretation of urine cadmium losses needs to be done with caution in elderly, diabetic, or hypertensive patients and in heavy smokers, as in these populations the cadmium excretion can be lower due to nephron loss. Elevated urinary excretion of an *N*-acetyl- $\beta$ -D-glucosaminidase and  $\beta$ 2-microglobulin has been used as an indicator of the toxic effects of cadmium on the kidney. Cadmium toxicity may also inhibit glucose reabsorption and reduce renal zinc reabsorption [201]. Thus it may be important to limit cadmium accumulation in MHD patients by avoiding smoking and restricting the intake of foods with high cadmium concentrations, which include shellfish, particularly Pacific oysters, and mushrooms, such as *Agaricus subrufescens* Peck.

### **Gadolinium**

Contrast agents containing gadolinium are used in MR imaging. Chelated gadolinium is administered as a paramagnetic agent for contrast-enhanced MR imaging. Gadolinium belongs to the lanthanide series of metals, and in its free form, it is highly cytotoxic. To minimize this toxicity, gadolinium is administered in a chelated form with high kinetic stability so that, under normal endogenous conditions, gadolinium dechelation usually would not occur. Most of the administered gadolinium chelate is excreted promptly through the urine, and the

half-life ( $t_{1/2}$ ) of gadolinium in patients with normal kidney function is about 60–90 minutes. Gadolinium contrast agents have been implicated in a serious fibrosing disorder known as NSF in patients with advanced kidney insufficiency [202,203]. Based on this evidence, the US Federal Drug Administration issued a black-box warning cautioning against the use of gadolinium contrast agents in patients who have an estimated glomerular filtration rate of less than 30 mL/min. Patients with NSF may develop fibrosis and ectopic calcification/bone formation in the dermis, subcutaneous tissues, heart, diaphragm, testes, and dura mater [202]. Clinically, this is manifested by edema, a plaque-like rash, woody induration of the extremities, tethering of the skin, and severely restricted joint mobility (Fig. 27.1). The pathology is characterized by the infiltration of CD34<sup>+</sup> spindle cells and macrophages, angiogenesis, and fibrosis [204]. Patients with kidney insufficiency are susceptible to gadolinium toxicity for a variety of reasons. First, administered gadolinium chelates are retained for prolonged periods in people with advanced CKD. The  $t_{1/2}$  for gadolinium can be prolonged for up to 32 hours in MHD patients and up to 20 days in CPD patients. Second, gadolinium contrast agents can induce iron mobilization that may, along with other endogenous metals such as zinc and calcium, induce dechelation of the gadolinium contrast (also known as transmetallation) and lead to tissue deposition of gadolinium phosphate. Among the gadolinium contrast agents, those with a linear structure (such as gadolinium-DTPA-BMA, Omniscan) are less stable than the macrocyclic agents and, thus, are more likely to cause NSF [205–207]. There is high mortality associated with NSF [208]. The use of sodium thiosulfate, rapamycin, and kidney transplantation may all have a role in the treatment of NSF [206,208]. Some studies have shown gadolinium accumulation in the brain of patients with normal kidney function who undergo repeated gadolinium-based contrast exposure.

FIGURE 27.1 Gadolinium-induced nephrogenic systemic fibrosis.

Gadolinium accumulates in cerebellar dentate nucleus and globus pallidus and other gray matter. The clinical significance of this accumulation is currently unknown [207,209].

### Germanium

Germanium is a nonessential trace element. Germanium-containing compounds were formerly used as dietary supplements and endogenous medicines and now are not as commonly used [210]. Germanium trioxide ingestion has been linked to renal tubular toxicity in humans [210–212]. Glomeruli, which may form foamy podocytes, and distal renal tubules, with acute tubular necrosis, are specifically affected. Tissue lipofuscin accumulation and associated neuromuscular weakness are other specific manifestations of germanium toxicity. Recovery of kidney function from germanium toxicity is slow and incomplete [213].

### Lanthanum

Lanthanum carbonate is a commercially available intestinal phosphate binder that is prescribed for patients with advanced CKD. Prolonged use of lanthanum-based phosphate binders in animals or humans with advanced CKD has been associated with an increase in serum lanthanum levels and accumulation of lanthanum in the bone [214]. In studies in animals with CKD, orally administered lanthanum has been demonstrated to accumulate in the liver and bone [215,216]. There are reports of GI deposition especially in the upper GI tract [217]. These deposits can be associated with such nonspecific symptoms as dysphagia, nausea, and gastritis; the long-term effects are not known [217].

### Lead

Lead toxicity can be acute, subacute, or chronic. Lead exposure and accumulation is a well-known cause of CKD [218,219]. Lead exposure can occur from occupational activities, through the intake of medications or local moonshine preparations, leached from cooking pots, ingestion of paint or other substances, or inhaled from lead-containing fumes, particularly during the time when lead-containing gasoline was used. Lead exposure is declining in the United States due to stringent occupational health oversights [220]. The clinical presentation of acute and subacute lead toxicity can include colicky abdominal pain, arthralgia, fatigue, changes in mental status, and anemia [221,222]. Studies suggest that up to 15% of patients diagnosed with essential hypertension may have a high lead burden [223,224]. Blood lead levels correlate with the risk of CKD in large population studies [225]. Serum and bone lead levels are increased in chronic dialysis patients [226,227] and in CKD patients [228].

Overt lead nephropathy presents as a chronic tubulointerstitial disease accompanied by glucosuria, aminoaciduria, low-molecular-weight proteinuria, hypertension, hyperuricemia, and gout (saturnine gout) [229]. Patients with lead toxicity may present with a neuropathy and may also have significant anemia; the red blood cells may have Howell–Jolly bodies. Lead that accumulates in bone can undergo recycling into the serum during states of increased bone turnover; for example, with hyperparathyroidism, and the mobilized lead may, in turn, cause clinical lead toxicity [230]. Low-level chronic lead exposure has been causally linked to the progression of kidney disease, and ethylene diamine tetra acetic acid (EDTA) chelation has been shown to retard the rate of progression [231].

### **Mercury**

Mercury (Hg) has been implicated in a variety of kidney diseases. Historically, mercury-containing compounds were used to treat syphilis and as diuretics [232,233]. Environmental and occupational exposures also contribute to increased body mercury burden and toxicity [234]. Inhalation of mercury vapors may also cause toxicity, including encephalopathy; for example, the Mad Hatter. Mercury has been implicated as a cause of acute tubular necrosis, glomerulonephritis, and CKD [235].

Human exposure to mercury salts occurs primarily through diet (contaminated fish), occupation, and environment; however, other forms of exposure such as through dental amalgams or the use of certain medicinal products are also known [236]. Upon ingestion, Hg is absorbed by the GI tract and deposited in the target organs, including the kidney. Eventually, mercury enters the renal tubular system and is transported to the intracellular compartment via different transporters, including organic anion transporters; the impact is worse in an already injured kidney and also in the aging kidney. Thus the renal effects of Hg exposure may be worse for people who already have CKD [235,237].

### **Molybdenum**

Molybdenum (Mo) is a constituent of molybdoenzymes that participate in oxidation–reduction reactions. It is also an important cofactor for xanthine oxidase and xanthine dehydrogenase. Molybdenum is known to be increased in the serum and hair of MHD patients [181]. Abnormal molybdenum accumulation may contribute to dialysis-related arthritis [238]. Molybdenum may interfere with normal copper homeostasis and increase urinary copper excretion. Excessive dietary molybdenum intake may result in gout-like symptoms [239]. Other consequences of increased molybdenum levels in patients with kidney

insufficiency are currently unknown. Molybdenum-based polyoxometalate nanoclusters may act as antioxidants and improve AKI induced by reactive oxidation species in mice [240].

### **Nickel**

Nickel (Ni) is a well-known environmental and occupational toxin that is prevalent in industries involved with nickel cadmium battery manufacturing and electroplating and electroforming. Nickel is known to be cytotoxic and carcinogenic. These effects of nickel appear to be mediated through multiple mechanisms, including oxidative injury from reactive oxygen species. The mitochondria-mediated apoptotic signaling pathway may also contribute to nickel toxicity [241].

Exposure to nickel could be a risk factor for kidney disease, as indicated by studies of urinary nickel. Urinary nickel levels are positively associated with albuminuria and  $\beta$ 2-microglobulinuria [242]. However, a defined role for nickel in human physiology or pathophysiology is lacking. Possible mechanisms of cellular injury may include the inhibition of fibrinolysis, thus promoting fibrosis (mimicking hypoxia), nickel-induced interference in the mitochondrial transport chain, or amplification of reactive oxygen species, which thereby exacerbate oxidative stress [243]. However, there are also data that nickel may cause cellular injury by oxidant-independent mechanisms [244].

Nickel levels are reported to be both lower and higher in patients with renal insufficiency [245]. Dermatitis due to nickel has been reported in MHD patients [246]. Nickel inhibits homocysteine synthetic pathways, and there is a negative correlation between serum nickel levels and serum homocysteine concentrations in MHD patients [247]. Nickel is an HIF mimetic and, therefore, has the potential to induce erythropoiesis [248,249]. Although there is an association between nickel compounds and both erythrocytosis and renal cell cancer in animals, strong evidence of such an associative link in humans is lacking [250,251].

### **Strontium**

Strontium (Sr) exposure can happen through diet (cereals, grains, seafood, and beverages) or the contamination of water or medications. Strontium is mainly absorbed through the GI tract and primarily eliminated through the kidneys [252]. It is mainly located in bone in humans. Since strontium is primarily eliminated by the kidneys, it accumulates in patients with reduced renal function [253]. Strontium accumulates in the serum, bone, and calcified tissues of uremic patients [254–256]. Strontium can interfere with osteoblast function and mineralization [256,257]. In animal models and human studies, the accumulation of strontium has been associated with osteomalacia [256–258].

## Vanadium

Vanadium (V) exists in several different states of oxidation and can have a valence of +2 to +5. Dietary sources of vanadium include cereals, mushrooms, spinach, and shellfish. There is evidence that serum vanadium levels are increased in MHD patients [47,259]. Vanadium has an effect on glucose metabolism similar to insulin and may have anabolic effects on muscle. Kidney toxicity due to chronic vanadium exposure has been described in animals, but evidence of such an association in humans is lacking [260]. Within the kidney, vanadium may have an affinity for the renal medulla. The mechanism of vanadium-induced renal injury is thought to be oxidative damage leading to lipid peroxidation, DNA degeneration, and denaturation of proteins which were increased in areas of elevated soil vanadium [261,262]. Vanadium has been an element of interest in studies of CKD of unknown origin that occurs in dry regions of Sri Lanka. The soil concentrations of vanadium in these regions were noted to be high, and the numbers of CKD patients were increased.

## Trace element abnormalities in renal-specific syndromes

Fig. 27.2 summarizes the abnormalities in trace elements and metals observed in various kidney-specific syndromes. The clinical and pathological effects of these associations, including proofs of causality, need additional investigation.

## Diagnostic and therapeutic approaches

Trace element disturbances should be considered in the differential diagnosis of individual clinical presentations as well as in the setting of epidemics. A high index of suspicion is critical for the diagnosis of trace element deficiencies and toxicities. Measurement of trace elements in serum and tissue samples can be helpful in reaching the correct clinical diagnosis. Serum, urine, and tissue concentrations of trace elements, particularly trace metals, can be measured fairly precisely by analytical methods such as atomic absorption spectroscopy (AAS) or inductively coupled mass spectrometry (ICP-MS). There is a high level of sensitivity with these methods; the measurements give values in parts per billion with AAS and in parts per trillion with ICP-MS. However, these are tissue-destructive techniques, and there is a lack of information concerning the distribution of trace elements within the tissues. To image the distribution of trace metals, several novel methods with high spatial resolution (i.e., the ability to image at submicron levels) in biologic samples are available [263]. These include electron microprobe, laser ablation microscopy-coupled ICP-MS, and synchrotron-based X-ray fluorescence.

Therapeutic approaches to correct trace element and metal deficiencies include dietary supplementation and the use of parenteral replacement as necessary. Toxic accumulation can be treated by removing the sources of toxins. The use of appropriate chelating agents to remove the toxic element must be considered. Successful

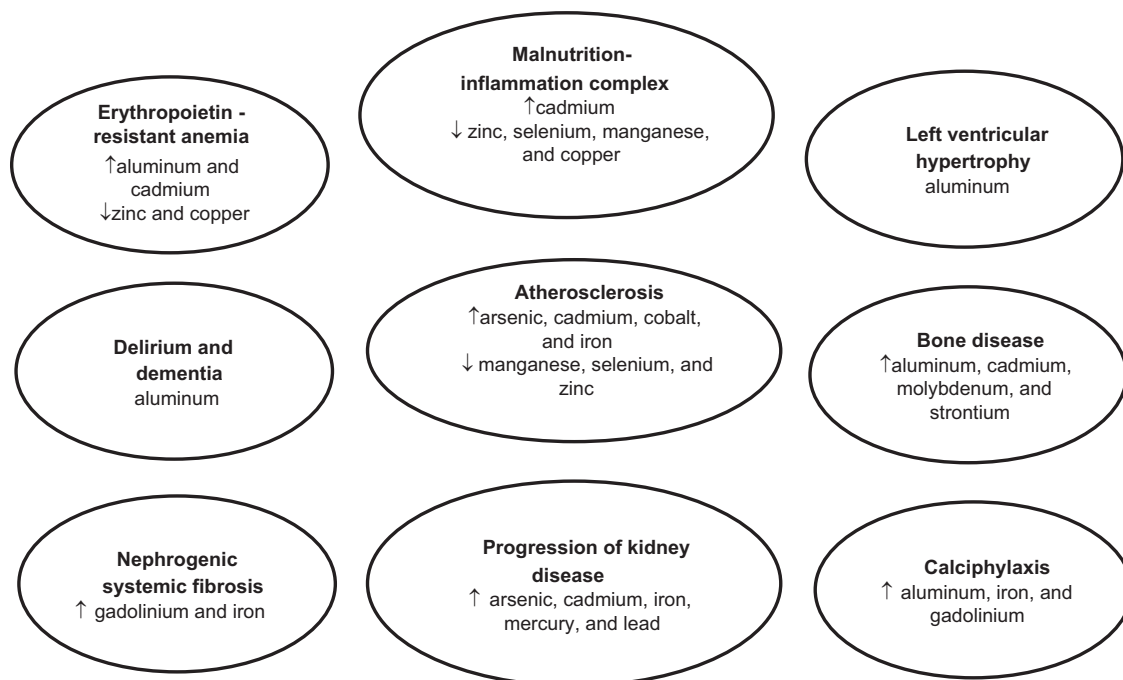

FIGURE 27.2 Trace element and trace metal abnormalities in different renal syndromes.

examples of chelation therapies include the use of deferoxamine to treat aluminum toxicity and the treatment of lead accumulation with EDTA chelation. Dialysis therapy, in conjunction with chelation therapy, may be effective for the treatment of some trace element toxicities in patients with advanced CKD or ESRD.

## Conclusion

This review summarizes the current knowledge of what is known and not known concerning alterations in trace elements, metals, and metalloids in kidney disease and kidney failure and the syndromes that may be associated with these altered trace element burdens. Of importance to nephrology is the recognition that perturbations in trace element metabolism may contribute to the pathogenesis of AKI (e.g., selenium deficiency) and CKD, including diabetic nephropathy (e.g., cadmium toxicity) and some of the major manifestations of the uremic syndrome such as anemia, EPO resistance, protein-energy wasting, the malnutrition–inflammation syndrome, and atherosclerosis. The intake of trace elements may be compromised due to CKD-driven anorexia superimposed on the dietary restrictions for CKD patients. Trace element losses are compounded by the need for diuretics and the losses that occur from renal replacement therapies. The risk factors for CKD compound the propensity for these derangements. GI absorption and metabolism also change in CKD patients and may lead to further alterations in the accumulation or deficiency of some trace elements.

The previous data support the suggestion that, for advanced CKD and chronic dialysis patients, routine monitoring of trace elements and targeted trace element supplements may be very beneficial. Further studies are needed to determine more exact therapeutic strategies. For people with kidney disease and kidney failure, more studies are also needed to examine the pathophysiological and clinical importance of altered serum concentrations or body burden of different trace elements, to develop more precise methods for assessing trace element burden, and to identify more effective therapies to treat trace element deficiency and excess.

## Introduction

The nephrotic syndrome is a consequence of the urinary loss of albumin and other plasma proteins of similar size and is characterized by hypoalbuminemia, hyperlipidemia, and edema formation [1–4]. The change in plasma protein composition has effects on immune function, risk of thrombotic events, and vascular injury. While albumin is the principal protein found in the urine, comprising between 75% and 90% of urinary protein, many other proteins are lost as well. These include immunoglobulins, transferrin, ceruloplasmin, and the binding proteins for vitamin D [5]. Albumin is the principal zinc carrying protein in plasma. Thus iron, zinc, selenium, boron, and copper may be lost in the urine and exhibit decreased plasma concentrations [6–9]. This results in decreased plasma levels of many proteins, including albumin and IgG [10]. The homeostatic response either to reduced plasma oncotic pressure ( $\pi$ ) or the loss of specific proteins leads to increased synthesis of proteins that are not lost in the urine, such as fibrinogen, and, thus, an increase in their plasma levels [11–14]. The levels of a variety of lipoproteins are also increased through mixed mechanisms involving a combination of increased synthetic rate and decreased clearance. Urinary losses of erythropoietin [15,16] and iron bound to transferrin [17] may lead to anemia. Other nutrients lost bound to proteins may cause reduction in trace metals or vitamins requiring replacement. Additionally, the net loss of amino acids may result in muscle wasting [18,19]. In addition to alterations in plasma protein composition,

both proteinuria and decreased plasma  $\pi$  lead to increased renal sodium retention as well as edema formation [20].

Hyperlipidemia in the nephrotic syndrome is characterized by increased triglyceride levels, increased levels of low-density lipoprotein (LDL) [21], and either a normal or reduced level of high-density lipoprotein (HDL) [22]. The atherogenic lipoprotein(a) [Lp(a)] is also increased as a consequence of an increased synthetic rate [23]. Disordered lipid metabolism imposes at least the potential for increased atherogenic risk to this patient population. Thus the primary manifestations of the nephrotic syndrome are altered plasma protein composition, decreased tissue protein pools, hyperlipidemia, edema formation, and loss of micronutrients and present a variety of therapeutic targets both for dietary intervention and pharmacologic intervention. Some of these are indeed useful, some are not, and some may increase injury.

## Albumin homeostasis in the nephrotic syndrome

Albumin is the most abundant protein in plasma. The most notable change in plasma protein composition in the nephrotic syndrome is hypoalbuminemia as a consequence primarily of urinary loss accompanied by an increase in the albumin fractional catabolic rate (FCR) [24]. This stands in contrast to the reduction in FCR that accompanies hypoalbuminemia in protein malnutrition [25,26]. The total albumin pool in a healthy adult is approximately 260 g/1.73 m<sup>2</sup>

with approximately 40% of that pool found in the vascular compartment [27]. Although albumin synthetic rate may be increased in the nephrotic syndrome, in some cases to more than twice the average rate [28], it is insufficient to replace the combined losses of albumin due to urinary excretion and increase in FCR. The reason why albumin levels are so sensitive to external loss, despite the rather large basal reserve, is that albumin has a relatively long half-life, approximately 12–20 days. Thus the fraction of albumin synthesized per day that is lost into the urine is quite high. Other proteins of similar size, such as prealbumin (transthyretin), have a more rapid turnover rate, and, thus, the fractional losses are much lower [29]. The basal synthetic rate of albumin is approximately 10–14 g/day; urinary losses in the average range for a nephrotic patient of 5 g/day represent 30% of the total daily synthetic rate. Furthermore, if albumin concentrations were not reduced, the urine losses would be even greater, assuming a constant renal clearance, putting a further challenge on the capacity of the liver to increase albumin synthesis in response to external loss. In experiments that we conducted, when albumin synthesis was increased by dietary protein supplementation, urinary albumin excretion increased as did the absolute and FCR of albumin, presumably representing increased renal catabolism of filtered albumin, while serum albumin concentrations actually decreased [28–30]. The lack of an increase in serum albumin concentrations was not only in part a consequence of increased renal albumin clearance, as well as an increase in the FCR of albumin, but also in part a consequence of the limits of hepatic albumin synthesis.

The mechanism of increased albumin synthetic rate is that of increased gene transcription [13,31]. While the direct stimulus for increasing albumin gene transcription is unclear, it may be linked to plasma  $\pi$ . It is accompanied by increased transcription of other liver-derived proteins, such as transferrin [32], that may be lost in the urine as is albumin. However, gene transcription of other proteins that are not lost in urine because of their large size, such as fibrinogen, may also increase [13,14,32]. The increased gene transcription of these additional proteins is accompanied by increased rates of synthesis that correlate with that of albumin [14]. In the case of fibrinogen, the plasma levels are actually increased as a consequence of this response in synthetic rate [14,33,34]. Synthesis of other proteins, such as apolipoprotein (apo) B [35] and Lp(a) [36], is also increased but does not appear to be correlated with that of albumin and will be discussed with regard to lipoprotein metabolism. Additionally, synthesis of other proteins, such as  $\alpha_2$  macroglobulin and  $\alpha_1$  inhibitor 3, is also greatly

increased [37] but not linked to the rate of albumin gene transcription [37–39].

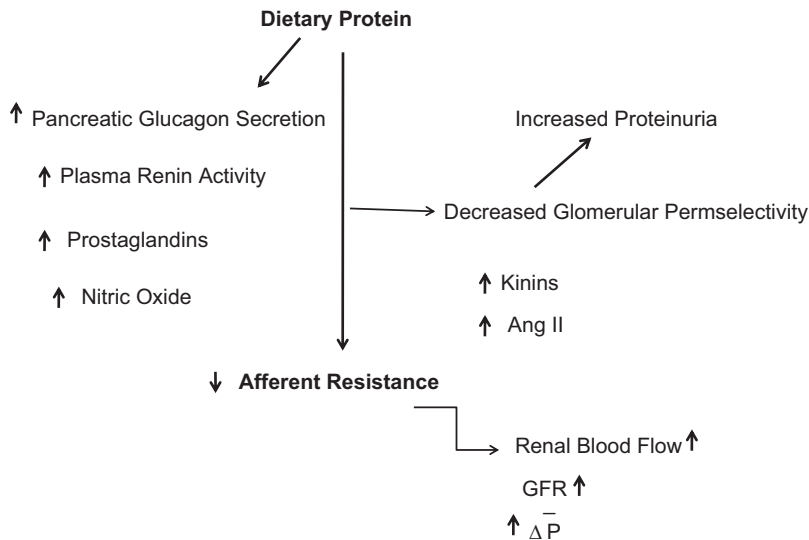

It should also be recognized that total-body protein synthesis does not increase in the nephrotic syndrome [40]. So the partial replacement of the plasma proteins lost in the urine is essentially enabled by reduced protein synthesis elsewhere, including in skeletal muscle, which may lead to total-body protein wasting.

### Dietary protein

The nephrotic syndrome may be compared to the type of protein–energy malnutrition known as kwashiorkor. In both cases plasma volume is expanded, albumin concentration is reduced, and albumin pools shift from the extravascular to the vascular compartment. Metabolic changes in the nephrotic syndrome include the depletion of plasma [28,30,41–44] and tissue protein pools [18,45,46]. However, unlike the nephrotic syndrome, in the case of protein malnutrition it is possible to correct all of the derangements by providing the needed proteins and calories. Although average values for proteinuria in the nephrotic syndrome range from 6 to 8 g/day [28,42,47,48], approximately the amount contained in a hen's egg, it has not been demonstrated that the replacement of protein loss can be achieved only by increasing dietary intake. In fact, dietary protein supplementation causes a greater defect in the filtration barrier of the glomerular capillaries [30,49] resulting in increased urinary protein losses (Fig. 28.1).

Yan et al. in a recent systematic review and meta-analysis, which analyzed 19 trials with 2492 subjects, documented that a low-protein diet reduced the rate of decline in renal functionality and the risk of kidney failure in chronic kidney disease (CKD) patients but did not produce a clear beneficial reduction in all-cause death events [53]. A low-protein diet also reduced the serum phosphorus concentration as well as body mass index. Hence, the nutritional status of CKD patients undergoing dietary protein restriction should strictly be monitored.

Dietary protein supplementation is followed rather promptly by an increase in both renal and splanchnic blood flow, an increase in glomerular filtration rate (GFR) in both humans [54] and experimental models in vivo [40,55–57], and by increased permeability of the glomerular capillary to protein. Consequently, urinary excretion of albumin increases when patients or animals affected by nephrotic syndrome have a high protein intake [28,30,58–60], although a part of increased albuminuria may be a consequence of the increased dietary acid load associated with protein intake, acting through an endothelin-mediated effect [61,62]. Moreover, the increase in albuminuria is not

**FIGURE 28.1** Dietary protein augmentation causes increased secretion of glucagon by the pancreas, alters activity of the renin–angiotensin axis, increases release of nitric oxide, and augments renal prostaglandin synthesis [50]. These, and possibly other hormones, increase renal blood flow, GFR, and under some circumstances, increase hydraulic pressure across the glomerular capillary. These processes combine to decrease the selectivity of the glomerular capillary and increase proteinuria. Pharmacologic intervention that blocks either kinin, Ang II or aldosterone prevents the increase in proteinuria [45,47,51,52]. *Ang II*, Angiotensin II; *GFR*, glomerular filtration rate.

due to increased plasma albumin levels. Studies have documented that plasma albumin levels either remain the same or decrease following dietary protein augmentation, and the plasma albumin level invariably increases when dietary protein is reduced [30,45,51,63]. Also the fractional rate of albumin catabolism, which is the fraction of the plasma pool catabolized per unit time, increases in nephrotic patients receiving a high-protein diet [28]. It might be more informative to examine the fractional excretion of a specific protein rather than the total excretion, to evaluate the magnitude of the injury to the filtration barrier as well as to provide prognostic information [64,65]. Increase of dietary protein intake has three different effects on albumin: (1) an increase in albumin synthetic rate, (2) an increase in the fractional renal excretion, and (3) an increased fractional rate of albumin catabolism. The second and third ones predominate. It is not clearly understood whether the increased fractional rate of protein catabolism is a direct effect of the dietary protein intake on the albumin catabolic rate in catabolic sites throughout the body, or, instead, whether this is a consequence of increased renal filtration of albumin followed by increased uptake and catabolism in the kidney of a greater amount of filtered albumin that may occur when eating a high-protein diet. However, the increased fractional rate of albumin catabolism, as well as the increased fractional renal clearance, will reduce albumin levels and reduce the positive effect of increased albumin synthesis. Of general metabolic and nutritional concerns, proteinuria is not associated with a change in entire body protein synthesis [19], so the net losses of protein determined by proteinuria result in the loss of tissue protein pools elsewhere.

In this regard, studies have investigated the molecular mechanisms underlying protein reabsorption in the

proximal tubule [66]. Megalin, the first receptor that has been studied, binds a variety of filtered molecules and is able to mediate endocytosis in the cytoplasmic tail. Cubulin is a peripheral membrane protein and is dependent on megalin to ensure internalization of its ligands. Independently of megalin, cubulin also interacts on the apical membrane with another protein, known as amnionless. The association between amnionless and cubulin is mediated through the epidermal growth factor–like repeats in cubulin [66]. Urinary albumin excretion can be increased in nephrotic mice by knocking out megalin and cubulin, increasing urinary albumin losses; however, there is no effect on serum albumin levels [67].

In physiological conditions, all filtered proteins are internalized by the receptor complex megalin/cubulin/amnionless, and the proteins are degraded within lysosomes. Normally, low–molecular-weight proteins are filtered, reabsorbed, and catabolized proximally. Even proteins as large as albumin are filtered and reabsorbed, but the fractional clearance is quite low, in the order of  $10^{-4}$ . When glomerular permselectivity is altered, the fractional clearance of larger proteins is increased, and the reabsorptive ability of the proximal tubular cells is overwhelmed. Moreover, proteins, normally completely catabolized by the proximal tubule, such as lysozyme [68], beta-2 microglobulin, *N*-acetyl-beta-D-glucosaminidase, or apo A–I, are found in the urine even though their glomerular clearance is not likely to be increased. Protein accumulation in lysosomes, due to increased protein internalization, is thought to mediate inflammation and fibrosis, eventually leading to renal failure [66].

Thus an increase in dietary protein promotes three independent processes that may modify plasma albumin levels in proteinuric subjects: (1) an increase of

albumin synthesis, tending to increase albumin mass; (2) an increase in the fractional rate of albumin catabolism, tending to deplete albumin mass; and (3) an increase in urinary loss, tending to decrease albumin mass. Theoretically, increased dietary protein intake might worsen proteinuria through two possible mechanisms. First, increased dietary protein intake increases glomerular capillary hydraulic pressure, which facilitates greater protein passage across the glomerular capillary wall; second, increased dietary protein intake may alter the permselectivity of the glomerular basement pore structure favoring larger pores. Chan et al. [69] found that increased dietary protein increases glomerular ultrafiltration pressure in nephrotic patients without modifying glomerular permselectivity. This would suggest that glomerular porosity is not influenced by dietary protein, and increased capillary pressure is the culprit for worsening of proteinuria. Meek et al. demonstrated in mice and in humans that a high-protein diet increased glomerular cell death and inflammation, indicating that high-protein diets may exacerbate early indicators of CKD [70]. In this light, dietary protein augmentation might worsen proteinuria by increasing glomerular pressures and by increasing porosity of the glomerular basement membrane in nephrotic patients [28] and animals [30].

The physiologic effects of amino acids on renal hemodynamics depend upon the specific amino acids fed or infused. Infusion of branched chain amino acids fails to increase GFR or renal blood flow in humans [54] or rats [71], while infusion of arginine causes important changes in renal hemodynamics [56], but not necessarily a change in urinary protein excretion. Thus neither an increase in dietary branch chain amino acids [71], nor an increase in dietary arginine or its potential precursors (proline, glutamate, and aspartate) [72], despite its role in nitric oxide synthesis, enhances albuminuria. In contrast, an increase in the dietary content of histidine, phenylalanine, tryptophan, tyrosine, lysine, glycine, alanine, serine, threonine, cysteine, and methionine combined has the same effect on elevating albuminuria as does an increase in the same quantity of dietary nitrogen with intact protein. Arginine supplementation has been shown to increase proteinuria in certain models of proteinuria in the rat [73], while a methionine–threonine-supplemented diet did not. A diet consisting of increased soy protein has been demonstrated to reduce reactive nitrogen species and renal injury in experimental models of the nephrotic syndrome [74]. The renal hemodynamic response to dietary protein may, therefore, depend on the specific amino acids in the proteins, rather than simply the amount of solute, total amino acids, protein, or nitrogen in the diet. A clinical trial exploring

the effect of dairy-free gluten-free protein sources in children with the nephrotic syndrome is currently being conducted [75].

Since the increase in GFR and renal blood flow may be prevented by somatostatin administration [57], it has been hypothesized that modifications in renal function induced by protein or amino acid administration may be in part hormonally mediated. An increase in dietary protein intake stimulates secretion of glucagon [55], corticosteroids [76,77], and dopamine [78] and enhances expression of the renin–angiotensin system [49], which may stimulate prostaglandin synthesis [50]. Increased pancreatic glucagon secretion seems to be necessary for the increase in GFR and renal blood flow [55] that follows dietary protein augmentation. Nevertheless, infusion of large amounts of glucagon exerted no effect on urinary albumin excretion [79]. Paller and Hostetter showed that high-protein diets increased the expression of the renin–angiotensin system in animals [49], and it is known that dietary protein augmentation alters glomerular permselectivity in subjects with nephrotic syndrome [58]. This observation was also confirmed in another study [47]. However, there are some nonconclusive data on the effects of a low-protein diet on renin secretion by the kidney. Martinez-Maldonado et al. [80] suggested that renal angiotensin-II activity is increased during dietary protein restriction and contributes to renal vasoconstriction and reduced filtration. This observation has not been confirmed by additional robust data, and most clinical and experimental studies suggest that protein administration increases plasma renin activity [47,49,52]. It is generally accepted that dietary protein intake leads to the activation of the renin–angiotensin system, increased renal blood flow and GFR, and worsening of proteinuria in patients with preexisting proteinuria. Also, the inhibition of the renin–angiotensin system with angiotensin converting enzyme (ACE) inhibitors can blunt or prevent the proteinuric effect of dietary protein in experimental renal diseases [81–83] and in nephrotic patients [47,48].

With regard to the changes in GFR with an amino acid infusion, the plasma levels of insulin, growth hormone, and glucagon all increase in response to the infusion, but only changes in glucagon exhibited a significant temporal relationship with changes in GFR [54]. A potential mediator of arginine-induced renal vasodilation may be NO, since arginine is the substrate for NO production. However, in experimental models, arginine supplementation ameliorated both proteinuria and hyperfiltration in diabetic rats and had no effect on urinary albumin excretion in rats with passive Heymann nephritis [72]. Thus as with the protein–renin interactions outlined earlier, there are conflicting data on the relationship between arginine, its

effect on renal hemodynamics, and how this translates into alterations in permselectivity.

Augmentation of dietary protein increases single-nephron GFR (SNGFR) and contributes to the loss of residual renal function. In addition, a rise in dietary protein increases protein filtration which exposes the renal epithelial cells both to potentially injurious proteins, such as complement components [84], as well as protein-bound injurious agents. An example of the latter is the fatty acids bound to albumin; with a rise in protein filtration, there is an increased delivery of free fatty acids to renal tubular epithelial cells which can lead to renal fibrosis [85–87]. Iron transported by transferrin is another example [17]. Urinary losses of both transferrin and erythropoietin can lead to anemia secondary both to iron losses and erythropoietin losses [15,16], and the tubular uptake of iron has been implicated as a cause of tubular fibrosis [88]. Glomerular damage and the concomitant increased glomerular permeability result in a marked increase in protein filtration and initially in augmented proximal tubular reabsorption of protein. Filtered proteins are reabsorbed, carrying iron [88,89], complement components [90], and biologically active lipids [91] into the renal interstitial space causing injury. Furthermore, there is an increase in angiopoietin-like 4 released from podocytes as a consequence of the delivery of fatty acids bound to serum proteins. Consequently, tubular protein overload occurs, leading to tubular cell injury and interstitial fibrosis [92]. This process probably involves the induction of cytokines and such other proinflammatory molecules as monocyte chemoattractant protein-1, osteopontin, and platelet-derived growth factor (PDGF) [93]. The trafficking and deposition of excess filtered protein may be a link between the initial glomerular injury and the subsequent development of tubulointerstitial disease. The resulting tubulointerstitial disease is a better predictor of the GFR and long-term prognosis than is the histologic severity of glomerular damage in almost all chronic progressive glomerular diseases, including IgA nephropathy, membranous nephropathy, membranoproliferative glomerulonephritis, and lupus

nephritis [94–96]. Furthermore, diets that are high in protein also generate more acid, inducing the kidney to increase ammoniogenesis. Accelerated rates of renal ammonia production due to the increased dietary acid loads accompanying a high-protein diet may also lead to renal injury, possibly by the activation of complement [96,97]. Higher hydrogen ion concentrations also enhance the generation of endothelin-1 in the kidney, which also promotes progressive renal injury as well as increasing proteinuria [61,62]. The reduction in urinary protein excretion that follows dietary protein restriction potentially can have a salutary effect on progressive renal injury through any or all of these mechanisms. Thus any process that reduces urinary protein losses should be encouraged.

Dietary protein restriction also reduces the synthesis and/or gene expression of several proteins that are thought to play a role in progression of renal injury, such as transforming growth factor- $\beta$  (TGF- $\beta$ ) [98], PDGF [99], and fibrinogen [33]. It is not known whether decreased expression of these genes is a direct result of dietary protein restriction or a consequence of secondary effects of a protein-restricted diet, such as decreased proteinuria with reduced contact of the interstitium to filtered plasma constituents or reduced renal ammoniogenesis (Table 28.1). In nephrotic patients the rate of fibrinogen synthesis is increased in proportion to the increased synthesis of albumin [100], and hyperfibrinogenemia may contribute to increased thrombosis associated with the nephrotic syndrome. Moreover, hyperfibrinogenemia may accelerate the progression of renal disease [101]. It is interesting to note that dietary protein restriction reduces the synthesis of both albumin and fibrinogen in nephrotic patients; however, the serum levels of albumin tend to increase, whereas serum fibrinogen levels decrease. Thus dietary protein restriction appears to have a favorable effect on both albumin and fibrinogen metabolism in nephrotic patients.

Several studies suggest that the composition of dietary protein may be as important as the absolute nitrogen content. In experimental studies in rats, dietary

protein augmentation with a mixture of certain amino acids causes a prompt increase in urinary albumin excretion [75], whereas other amino acids, specifically branched-chain amino acids, arginine, proline, glutamine, glutamate, aspartate, or asparagine, are devoid of an effect on proteinuria [83]. Studies by D'Amico et al. [102] and Walser [103] suggest that dietary protein composition may also be of importance in humans with renal disease. D'Amico et al. found that when patients with the nephrotic syndrome were fed a vegetarian soy diet, urinary protein excretion decreased as did blood lipid levels [102]. The diet was also low in fat (28% of calories) and of low-protein content (0.71 g protein/kg normal body weight). The salutary effects of soy diets in nephrotic patients may be a consequence of the amino composition in these diets, although differences in lipid composition or in protein intake may also explain the apparent benefit of these diets as well. In a subsequent study, fish oil was added to the vegetarian soy diet. The addition of fish oil did not give any additional benefit [104]. Administration of an amino acid/ketoacid-supplemented vegan diet also reduces proteinuria and increases serum albumin levels [105]. Walser et al. showed that supplementing a very low-protein diet (0.3 g/kg per day) with essential amino acids or ketoacids not only reduced proteinuria in patients with the nephrotic syndrome but also maintained or improved GFR. In fact, this regimen may induce a prolonged remission, even if the patients resume ingesting a normal diet. As noted by the investigators, the mechanism for this response is not known [106].

### Effects of the nephrotic syndrome on solid tissue proteins

While it is more difficult to quantitate the losses of tissue protein, heavy proteinuria has been strongly associated with sarcopenia [46,107,108]. Rats with Heymann nephritis gain weight at a significantly lower rate than normal rats [45]. While increasing dietary protein from 8.5% casein to 40% causes a significant increase in growth velocity in normal rats, dietary protein augmentation causes significantly less improvement in growth rate in rats with Heymann nephritis. Nephrotic rats fed 40% protein gain weight significantly more slowly than do normal rats fed 8.5% protein [45], even though the difference in protein intake between 8.5% and 40% is many times greater than the urinary protein lost in either nephrotic group. When dietary protein is increased from 8.5% to 40% protein, total carcass (mainly muscle) protein pools are increased in normal rats. In contrast, none of the increase in weight of nephrotic rats fed 40% protein is

found in muscle but instead is in viscera, namely, liver and kidney [45]. Most of the increased protein nitrogen consumed when high-protein diets are fed to these animals is excreted in the urine as urea [79,109].

Nephrotic rats have a reduced rate of muscle protein synthesis [18] and an increased rate of hepatic protein synthesis, providing a mechanism for growth impairment in these animals. Total-body protein synthesis is the same in nephrotic and healthy rats [110], yet the nephrotic animals must replace the large amounts of protein lost in the urine, which they do through increased hepatic protein synthesis [18]. Similarly, total-body protein synthesis is the same in humans with the nephrotic syndrome as in controls, despite their urinary losses of protein [19]. Amino acid oxidation is reduced in nephrotic animals in response to the urinary protein losses [110]. It is unknown whether this represents an alteration in muscle metabolism [46,111].

These observations have supported the notion that dietary protein augmentation does not replete protein pools that have been depleted in nephrotic patients or animals; but in addition, high-protein diets are detrimental in that they cause progressive renal injury in a variety of experimental renal diseases in animals [1] and in humans [112–114]. Since a high dietary protein intake is of no benefit in nephrotic patients or animals, a high-protein diet, or completely unrestricted diet with regard to protein intake is not recommended.

The long-term safety of a low-protein diet is uncertain. Using leucine turnover rates as a marker of protein breakdown, Lim et al. [115] noted that nephrotic patients maintained positive nitrogen balance and had lower rates of protein degradation on a modestly restricted protein diet (0.9 g/kg/day) over a period of 35 days. Similarly, Maroni et al. [116] demonstrated that nephrotic patients ingesting 0.8 g/kg/day over a period of 24 days maintained positive nitrogen balance. The principal compensatory response to dietary protein restriction was a decrease in amino acid oxidation. In addition, the investigators noted an inverse correlation between leucine oxidation and the degree of proteinuria, suggesting that proteinuria is a stimulus to conserve essential amino acids. Thus modest protein restriction may be a safe and an effective therapy to reduce proteinuria. However, there are no data on the effects of long-term protein restriction to amounts much less than 0.8 g/kg/day in nephrotic patients. It is, therefore, probably not justifiable to place patients who are heavily proteinuric on diets that contain less than 0.8 g/kg/day except on an experimental basis.

It is still not known whether specific protein sources are clinically superior to others, although fruits and vegetables, and especially soy protein, have been evaluated in both animal [117] and human studies [102,104]. The amino acid composition of the protein

may turn out to be as important as the quantity of protein in the diet, but no specific recommendations can be made at this time with regard to the amino acid composition of the diet. However, it is probably not harmful to place patients on a largely vegetarian diet, considering the low fat content and the excellent results reported by D'Amico et al. [102].

### **Dietary proteins as potential allergens responsible for renal disease**

Agents that may be potential causes of the nephrotic syndrome, when it occurs without systemic disease, are largely unknown. In some patients with minimal change disease and the nephrotic syndrome or patients with mesangial proliferation, exposure to specific dietary proteins, such as cow's milk, has been implicated as a cause [13–17,105]. Bovine serum albumin and casein have also been identified as an allergen in a patient with immune complex glomerulonephritis. Clinical remission followed the removal of the offending agent from the diet.

Abdel-Hafez et al., in a review article, showed that although some cases of idiopathic nephrotic syndrome may be related to allergies, clear data that it is a type of allergic disorder or that it is caused by a specific allergen are lacking [118]. The authors in this review commented that the proteinuria and high IgE levels in patients with idiopathic nephrotic syndrome are determined by greater interleukin 13 (IL-13) levels. Studies also indicate that IL-13, identified as stimulator of IgE response, may mediate urinary protein losses in patients with minimal change disease due to its ability to induce CD80 expression on the podocyte [118].

There is an association of gluten enteropathy with IgA deposition in the glomeruli and the development of IgA nephropathy, and this may be due to an allergic reaction to gluten in the diet [106]. Overall, it is unclear what fraction of patients with the nephrotic syndrome have food allergy as a causative factor. Nevertheless, the possibility that food allergy might be responsible for the development of specific renal diseases is rarely considered by most clinicians and may be of overlooked importance. More recently, a case–control study did not conclusively confirm a clinically significant role for celiac disease or immune reactivity to gluten in IgA nephropathy [119].

### **Effects of lipids on renal disease and nephrotic syndrome**

Increased dietary lipid intake is associated with increased lipid levels, both of triglycerides and LDL, and higher levels of inflammatory cytokines in

experimental models of the nephrotic syndrome compared to animals fed a high protein, low-fat diet [120]. High-lipid diets are also associated with an increased risk of glomerulosclerosis in experimental animal models [121]. Subjecting rats with adriamycin-induced nephrotic syndrome to a higher lipid diet increases urinary protein excretion and exacerbates mesangial proliferation [121,122], suggesting that hyperlipidemia, in addition to being caused by the nephrotic syndrome, contributes to renal injury. Simvastatin treatment was also found to reduce glomerulosclerosis in the same rat model of renal injury [123]. A high-fat diet leads to renal tubular lipid deposition through the activation of the sterol regulatory element binding protein-1 and TGF- $\beta$ 1 [124].

It is generally accepted that both qualitative and quantitative alterations in blood lipids cause macrovascular disease, and hyperlipidemia caused by the nephrotic syndrome is no less dangerous than hyperlipidemia due to other causes. In the process of atherogenesis, lipid-laden macrophages accumulate in the vessel wall, followed by intimal hyperplasia, and ultimately by atherosclerosis. Recent works from several laboratories [125–127] suggest that similar changes may occur in the microvasculature of the kidney, specifically the glomerular mesangium. As detailed earlier, increasing dietary lipids in experimental models of the nephrotic syndrome leads both to increased glomerular injury and lipid accumulation in tubular endothelial cells [120,121]. Delivery of free fatty acids by filtered albumin increases podocyte injury [128]. Al-Shebeeb et al. [126] found that focal glomerular sclerosis occurred in guinea pigs fed a high-cholesterol diet for 70 days. The animals developed proteinuria and hematuria. A high-cholesterol diet also caused albuminuria, accelerated focal glomerulosclerosis, and increased glomerular capillary pressure in rats [125].

The obese Zucker rat develops spontaneous hyperlipidemia, proteinuria, and progressive glomerulosclerosis. These processes can be attenuated by cholesterol-lowering drugs [125,129]. It is interesting to note that glomerular capillary pressure and SNGFR are within the normal range, suggesting that hyperfiltration does not mediate the glomerular injury caused by hyperlipidemia [125]. Diamond et al. [127] found that rats with the nephrotic syndrome induced by puromycin aminonucleoside (PAN) had more proteinuria and a lower GFR when fed a high-cholesterol diet as compared to nephrotic rats eating a regular diet. The glomeruli in rats fed a high-cholesterol diet were more sclerotic and had mesangial cell proliferation and foam cells. Lowering plasma cholesterol by the administration of cholestyramine resin attenuated both acute and chronic proteinuria in these animals [125]. It has been hypothesized that increased blood lipid levels,

either from dietary cholesterol or from hyperlipidemia caused by the renal disease, may play an important role in intensifying the rate at which established renal diseases progress [125,130] and may even initiate glomerular injury [126,131]. These changes could be due to either hemodynamic changes or the direct injury that follows the uptake of lipids by the glomerulus.

The oxidation of circulating lipids may play a role in progressive renal injury. Glomerular macrophages endocytose LDL both through specific LDL receptors and through the nonspecific scavenger system. It is known that hyperlipidemia activates mesangial cells (which have LDL receptors). This leads to the stimulation of mesangial cell proliferation and to increased production of macrophage chemotactic factors, fibronectin (a component of the extracellular matrix), and reactive oxygen species [132–134]. Both increased mesangial lipid deposition and enhanced expression of LDL receptors on mesangial and epithelial cells have been demonstrated in patients with chronic glomerular diseases. Unregulated absorption of oxidized LDL may then lead to an uncontrolled increase in intracellular cholesterol [135], because oxidized lipids bypass the protective mechanism that regulates LDL uptake. After endocytosis, cholesterol is esterified by acetyl CoA cholesterol acyltransferase to form the insoluble cholesterol oleate ester [135]. This process results in creation of foam cells in the glomerulus analogous to that of early atherosclerosis in blood vessels. Thus the oxidative state of lipids may also play a role in their nephrotoxicity; hence, anti-oxidant drugs might prove protective.

These studies on animals are supported in part by further, albeit uncontrolled, observations in patients in which reducing lipid levels with an HMG CoA reductase inhibitor reduces proteinuria or slows the rate of progressive injury [136]. Hypercholesterolemia is also a separate independent risk factor for the progression of renal injury in diabetic patients [137].

Lipids represent a wide variety of substances, including steroids, saturated and unsaturated fatty acids, phospholipids, and other compounds, many of which have either direct biological activity or are precursors of important biologically active metabolites. Much attention has been focused on the effect of polyunsaturated fatty acids (PUFAs) on renal hemodynamics and on the manifestations of renal injury.

### Disordered lipoprotein metabolism in the nephrotic syndrome

Lipoprotein metabolism is disturbed, in part, as a consequence of both hypoalbuminemia with resulting decreased plasma oncotic pressure ( $\pi$ ) and independently as a consequence of urinary protein loss [138].

Of these two related processes, urinary protein losses predominate in the causal pathway. Low plasma  $\pi$  increases hepatic synthesis of apo A–I, apo B, and apo E, while decreased clearance of triglyceride-rich lipoproteins is predominately a consequence of proteinuria [139]. Albumin, and perhaps other proteins as well, increases the delivery of free fatty acids bound to filtered proteins to podocytes, which leads to the release of angiopoietin-like 4, a strong inhibitor of lipoprotein lipase (LPL) [13,140–142]. This results in increased plasma triglyceride-rich lipoproteins as a consequence of inhibition of LPL, which greatly prolongs the half-life of triglyceride-rich lipoproteins. Plasma LDL levels are also increased as a consequence of increased synthesis of apo B [35] as well as reduced LDL clearance due to an increase in proprotein convertase subtilisin/kexin type 9 (PCSK9) levels [143]. Both secretion and hepatic transcription of LDL are increased in the nephrotic syndrome in rat models [12].

### The effect of altered glomerular permselectivity on lipid metabolism

The primary drivers of increased lipid levels in the nephrotic syndrome are decreased clearance of triglyceride rich lipoproteins (VLDL, chylomicron remnants) as a consequence of decreased LPL activity and both increased synthesis and decreased clearance of LDL. LPL is primarily decreased as a consequence of the release of angiopoietin-like 4 protein from podocytes due to enhanced exposure to free fatty acids as a result of the increased filtration of albumin [144]. An identical defect in VLDL clearance is observed following the onset of proteinuria in rats with hereditary analbuminemia and in otherwise normal rats following the onset of proteinuria. These findings demonstrate that renal loss of protein rather than renal loss of albumin is the trigger for this hyperlipidemia. Indeed, if increased fatty acid delivery to podocytes is the mechanism for increased plasma lipid levels, fatty acids bound to albumin is not the only pathway leading to this response [139]. Plasma LDL is increased both as a consequence of increased synthesis [35,145] and decreased clearance. Reduced LDL clearance is linked to increased release of PCSK9 by the liver [12,143]. Increases in albumin gene expression parallel the increased gene transcription of such other proteins as transferrin, fibrinogen, and apo A1 [13]. It is unclear whether an increased production of PCSK9 is affected by a similar mechanism, but clearly increased hepatic release of this protein plays a role in reduced LDL clearance and increases in plasma LDL levels.

As mentioned earlier, hyperlipidemia is found in rats with hereditary analbuminemia [138,146,147].

These animals have a reduced plasma  $\pi$  and only trace amounts of albumin in their plasma. The genetic disorder is a seven nucleotide deletion isolated to the MN intron of the albumin gene creating a splicing defect during albumin mRNA processing [148]. Although this finding would suggest that reduced plasma  $\pi$  or reduced plasma albumin concentration alone is the signal to induce the lipid abnormalities described earlier, the catabolism of both VLDL and chylomicrons is normal in these animals [138]. A severe defect in catabolism of both of these lipoproteins follows the onset of proteinuria [149] suggesting that proteinuria plays a role in the pathogenesis of disordered lipid metabolism independent of the serum albumin levels or  $\pi$ . Supporting this hypothesis is the observation that reducing albuminuria by administering ACE inhibitors or dietary protein restriction reduces blood lipid levels [138,149,150] even if neither plasma albumin concentration nor plasma  $\pi$  is increased.

### Cardiovascular effects of hyperlipidemia in the nephrotic syndrome

Accelerated atherosclerosis occurs in patients with proteinuria and hyperlipidemia and is probably responsible for the sharply increased incidence of cardiovascular disease and stroke in the nephrotic syndrome [151,152]. Hyperlipidemia is also thought to worsen glomerulosclerosis and enhance progression of glomerular disease [153]. One study reported an 85-fold increase in the incidence of ischemic heart disease in patients with nephrotic syndrome [154]. This is not surprising when one considers that serum HDL, and specifically the HDL<sub>2</sub> fraction, is reduced [22,155] while serum LDL, intermediate-density lipoprotein, and VLDL fractions are high. It is not yet known what the biological significance is of the increased serum Lp(a) levels in the nephrotic syndrome. Lp(a) is a powerful atherosclerotic risk factor when it occurs genetically [156]. However, these high Lp(a) concentrations occur in combination with the low-molecular-weight isoform. Thus it is difficult to know whether it is the increased concentration or the specific type of isoform of Lp(a) that promotes atherogenesis. Some studies suggest that the low-molecular-weight isoform per se may confer the increased atherosclerotic risk [157]. It remains to be determined whether the elevated serum levels of Lp(a) in nephrotic patients also contribute to the increased rate of atherosclerosis observed in this population. While the plasma concentrations of most intermediate-sized proteins are reduced, the serum concentrations of many larger proteins, such as fibrinogen and prothrombin [34], are increased and potentially may play a role in the hypercoagulable state

associated with this syndrome [158] and contribute to atherosclerosis. Hyperlipidemia, therefore, is a serious consequence of proteinuria and should be addressed to protect patients from atherosclerosis. Hyperlipidemia may also contribute to the progression of the renal disease [125,130] and may even initiate renal injury [126,131].

### Thromboembolic complications

Dyslipidemia can result in acceleration of atherosclerosis as well as increased risk of myocardial infarction or stroke. Moreover, dyslipidemia during nephrotic syndrome may have a causative role in the increased risk of thrombosis associated with this syndrome. Dyslipidemia is one of the more relevant risk factors associated with atherothrombotic disorders [159]. Diuretic use and intravascular volume reduction, protein C and protein S deficiencies, and antiphospholipid antibodies are relevant contributing factors to thromboembolic complications [160]. The deep veins of the lower limb are the most common sites of thrombosis in adults affected by nephrotic syndrome. Renal vein thrombosis is less common, but pulmonary embolism can occur and is most likely to be due to deep venous thrombosis. A retrospective study analyzing diagnostic codes of patients at the time of their hospital discharge showed that deep vein thrombosis occurred in 1.5% and renal vein thrombosis in 0.5% of patients affected by nephrotic syndrome [161].

Another large retrospective cohort study assessed the risk of venous and arterial thromboembolism in patients with nephrotic syndrome. There was a high risk of asymptomatic venous thromboembolism and arterial thromboembolism during the first 6 months of presentation of the nephrotic syndrome. The ratio of proteinuria to serum albumin levels predicted venous thromboembolism, whereas estimated GFR and the traditional risk factors for atherosclerosis were associated with arterial thromboembolism [162]. Currently, there are no randomized control trials that have examined the clinical indications for prophylactic anticoagulant therapy or for how long such therapy should be given. General factors such as the presence of edema, immobility, and a previous history of thromboembolic events are commonly considered when deciding whether to initiate anticoagulant therapy.

### The role of polyunsaturated fatty acids

Prostaglandins and thromboxane are metabolic products of PUFAs. They include both vasoconstrictors, such as thromboxane A<sub>2</sub> (TXA<sub>2</sub>), and vasodilators, such as PGE<sub>2</sub> or PGI<sub>2</sub>, and they may exert

important hemodynamic effects. The effects of oxidized lipoproteins may also be mediated by these autocoids [163].

Eicosanoids are derived from PUFA present in the diet, because PUFA cannot be synthesized by mammals. Thus eicosanoid metabolism can be manipulated nutritionally [164]. Lipids derived from marine sources are rich in omega-3 PUFA (e.g., eicosapentaenoic acid), while those derived from vegetable oils are enriched with omega-6 PUFA (e.g., arachidonic acid). Eicosapentaenoic acid competes with arachidonic acid as a substrate for cyclooxygenase and lipoxygenase. Cyclooxygenase converts arachidonic acid to the diene metabolites (e.g.,  $\text{PGI}_2$  and  $\text{TXA}_2$ ) and eicosapentaenoic acid to triene metabolites (e.g.,  $\text{PGI}_3$  and  $\text{TXA}_3$ ), respectively [165,166]. Lipoxygenase converts arachidonic and eicosapentaenoic acids to the four and five series of leukotrienes, respectively [167,168].  $\text{TXA}_2$ , an arachidonic acid metabolite, is a potent vasoconstrictor, whereas  $\text{TXA}_3$ , a metabolite of eicosapentaenoic acid, is biologically inert [169]. In contrast, the vasodilators  $\text{PGI}_2$  and  $\text{PGI}_3$  are equipotent [165].

Changes in the generation of vasodilatory prostaglandins ( $\text{PGE}_2$ ,  $\text{PGI}_2$ ) and vasoconstricting cyclooxygenase metabolites ( $\text{TXA}_2$ ) can occur during renal injury or during physiologic stress, such as plasma volume contraction. While changes in eicosanoid metabolism can contribute to the GFR adaption to renal injury or plasma volume contraction, they may also play a pathogenic role. Because of the differences in biological activity of their vasoconstrictive and vasodilatory metabolites, substitution of eicosapentaenoic acid for arachidonic acid in the diet may alter the expression of renal injury.

The metabolic effects of dietary PUFA, particularly fish oil, have been studied in a variety of experimental models of renal disease, including the nephrotic syndrome [170–172]. In adriamycin-induced nephrosis in the rat, Ito et al. [173] found that plasma cholesterol, triglycerides, creatinine, and proteinuria were significantly lower in rats fed fish oil than in rats fed beef tallow. Glomerular hyalinosis and endothelial swelling were also less in the fish oil-fed rats and were correlated with the changes in plasma triglycerides and cholesterol.

In a subsequent study of the same model, dietary fish oil induced a dose-dependent reduction in glomerular synthesis of dienoic eicosanoids,  $\text{PGE}_2$ , 6-keto- $\text{PGF}_{1\alpha}$  (a stable metabolite of  $\text{PGI}_2$ ) and  $\text{TXB}_2$ , a stable product of  $\text{TXA}_2$ . Fish oil also decreased the generation of  $\text{TXB}_2$  from platelets. In studies of rats with nephrotic syndrome induced by adriamycin, Barcelli et al. [174] reported that dietary fish oil (a source of omega-3 PUFA), evening primrose oil (a source of omega-6 PUFA), or a mixture of these two

PUFAs reduced plasma triglyceride and cholesterol levels as compared to rats fed beef tallow. The fatty acid composition of the kidney was different in each dietary group, but neither the magnitude of proteinuria nor changes in plasma creatinine were affected by dietary fish oil. In another model of progressive renal injury in the rat, partial renal ablation, Scharschmidt et al. found that diets supplemented with fish oil accelerated the course of renal injury [171] and caused increased mortality.

In studies involving human subjects, Gentile et al. [104] added 5 g of fish oil per day to the diet of patients with the nephrotic syndrome who had been maintained on a soy vegetarian diet. These investigators found no beneficial effect of the fish oil on either proteinuria or on blood lipids when compared to patients maintained on the soy diet without fish oil supplementation. In contrast, Hall et al. [175] found that 15 g of fish oil per day caused a decrease in plasma total triglycerides and in LDL triglycerides and an increase in plasma LDL cholesterol. Donadio et al. [176] treated 55 patients with IgA nephropathy and proteinuria with 12 g of fish oil per day in a prospective, randomized, placebo-controlled study. They found a significant reduction in the rate of progression of renal disease using a 50% increase in serum creatinine concentration as a study end point. However, there was no significant effect on proteinuria or blood pressure. These studies suggest that while alterations in dietary PUFA may alter some manifestations of the nephrotic state, the effects are dependent upon the model being investigated; and the possible therapeutic value of PUFA should still be viewed with caution. The effects of these PUFA supplements may be neither predictable nor salutary for all patients with renal disease.

Harris et al. [177] reported that a diet entirely devoid of essential fatty acids provided renal protection by inhibiting macrophage function. While vasoactive lipids probably do play a role in altering the course of a variety of renal diseases, the effects of specific alterations in the composition and amounts of dietary PUFAs on the course of renal diseases in humans are not completely known. Thus there is no strong evidentiary basis at this time to recommend dietary PUFA supplements to patients with the nephrotic syndrome, with the possible exception of heavily proteinuric patients with IgA nephropathy [178]. Even here the value of using fish oil remains questionable. Recently, it has been shown that there is a lack of knowledge on the role of the fatty acid profile on the course of disease, independent of supplementation, and the type of renal disease, including the nephrotic syndrome [179]. In fact, the majority of studies analyzed the response to PUFA supplementation without

considering the impact of the basal fatty acid metabolism on the effects of supplementation.

### **Derangements in divalent cation metabolism in the nephrotic syndrome**

The nephrotic syndrome is characterized by the urinary losses of a variety of proteins in addition to albumin. These losses are potentially accompanied by excretion of metabolites normally bound to the protein. Transferrin is a glycoprotein bound to iron. The loss of iron in the urine provides the potential both for developing iron deficiency and the toxic presentation of iron to renal tubular cells where its uptake may contribute to renal fibrosis [89] [see [Chapter 8: Catalytic \(Labile\) Iron in Kidney Disease](#)]. Urinary transferrin loss is accompanied by an increase in the rate of transferrin synthesis [180] and gene expression [13,32], both of which are correlated with either the rate of albumin synthesis or with gene transcription for albumin rather than with serum iron or markers of inflammation. This suggests that the regulation of the transferrin gene in the nephrotic syndrome is driven in response to plasma oncotic pressure rather than as a homeostatic response to iron losses. Increased synthesis of transferrin is accompanied by increased transferrin losses, thereby exacerbating iron loss [180]. Anemia may also be a consequence of the urinary loss of another glycoprotein that is of a size likely to pass the glomerular filtration barrier in the nephrotic syndrome, erythropoietin [15,181,182]. Indeed, plasma levels of this protein are reduced in both nephrotic patients [181] and rats [15], and it does not appear that synthesis of erythropoietin is increased in response to its urinary loss [15]. There are no prospective randomized studies of the effect of administration of either iron (potentially harmful) or erythropoietin (expensive and inconvenient) to anemic patients with the nephrotic syndrome to guide clinical practice.

While the treatment of iron deficiency is necessary, the primary target for therapy must be the reduction of urinary protein loss. The treatment of anemia may require both iron supplementation and administration of erythropoietic stimulating agents. However, anemia is not the only adverse effect of urinary iron loss. Increased filtration of iron is accompanied by increased tubular reabsorption, which can lead to fibrosis [183–185]. Thus administration of iron to correct iron deficiency mediated by urinary transferrin loss in the nephrotic syndrome may not be without risk [see [Chapter 8: Catalytic \(Labile\) Iron in Kidney Disease](#)].

In addition to iron deficiency, urinary copper losses resulting from the loss of the copper-binding protein, ceruloplasmin, can lead to a significant depletion of this trace metal [186]. Zinc is bound to albumin, and

the levels of this divalent cation are found to be reduced in subjects with the nephrotic syndrome, even when consuming high-zinc diets [187]. Loss of zinc has been associated with skin lesions [188], but this complication is uncommon [187]. It is also unclear what role urinary zinc losses play in generating zinc depletion and what contribution is provided by alterations in gut zinc absorption [189]. In contrast to zinc, urinary copper losses, resulting at least in part from increased urinary ceruloplasmin excretion, are associated with both anemia and leukopenia [9,190,191]. Documented zinc deficiency is probably a consequence of reduced intestinal absorption of zinc in conjunction with excessive urinary loss [192]. The effect of proteinuria on zinc metabolism has been largely ignored, and it is not known to what extent zinc depletion plays a role in the clinical manifestations of the nephrotic syndrome.

Hypocalcemia is well recognized in nephrotic patients [193–196] and includes reduced serum vitamin D levels, specifically 25-hydroxyvitamin D and serum ionized as well as total calcium. Hypocalcemia does not result entirely from low serum albumin levels and a reduction in the amount of calcium-bound albumin, since plasma vitamin D is reduced [5,192,193,197]. The decrease in serum calcium concentration correlates with urinary albumin excretion [192]. Plasma albumin and vitamin D concentrations correlate closely. Vitamin D-binding protein is present in the urine of nephrotic patients [5,197], although plasma levels are not decreased. Serum vitamin D levels normalize when proteinuria resolves [193,197]. Labeled vitamin D appears rapidly in the urine of nephrotic subjects [194], suggesting that urinary vitamin D loss is the cause of hypovitaminosis D in these patients. Hypovitaminosis D is not primarily the result of loss of renal mass, since plasma vitamin D levels are also low in nephrotic patients with normal renal function [193–195]. The hypovitaminosis D of the nephrotic syndrome may result in rickets, especially in children [194,196]. Nephrotic patients malabsorb calcium [175], a defect that can be corrected by exogenously administered vitamin D [194]. It is not known whether synthesis of vitamin D-binding protein is altered in response to its urinary loss or whether it is modulated by dietary protein intake. Unlike many of the other manifestations of the nephrotic syndrome, hypovitaminosis D can be managed with replacement therapy.

### **Derangements in salt and water metabolism in the nephrotic syndrome (volume homeostasis)**

One of the defining features of the nephrotic syndrome is edema formation. This is the result of two separate processes, either of which may be dominant. The decrease in plasma oncotic pressure resulting from the loss of

albumin and other proteins of similar size would favor edema formation, since it would tend to result in a loss of the difference in oncotic pressure ( $\Delta\pi$ ) between plasma and interstitial space, favoring the flux of fluid from the plasma compartment into the extravascular space (Fig. 28.2). However, the loss of albumin from the plasma compartment is accompanied by transfer of albumin from the extravascular pool into plasma via increased lymphatic return [198] providing a physiologic response that partially balances the decrease in plasma  $\pi$ . Indeed, in health, approximately 60% of the total-body albumin pool is extravascular [30,199], and the extravascular pool is more significantly depleted of its albumin mass than is the plasma pool as a consequence of increased lymphatic return of extravascular fluid [198,200]. This reduces the effect of reduction in plasma albumin concentration with

regard to the difference between plasma and interstitial oncotic pressure ( $\Delta\pi$ ). If the entire basis for edema formation was a decrease in  $\Delta\pi$  that was great enough to increase the flux of fluid from the vascular compartment into the interstitium to such a rate that it could not be compensated for by increasing lymphatic return, one would anticipate that nephrotic patients would have elements of plasma volume depletion, with increased plasma renin activity, aldosterone, and norepinephrine. While this is found in some subjects, especially among children with some forms of the nephrotic syndrome, it is more the exception.

The second mechanism for edema formation is that of primary renal sodium retention as a consequence of activation of the sodium channel in the collecting duct (ENaC) which can result in plasma volume expansion (Fig. 28.3).

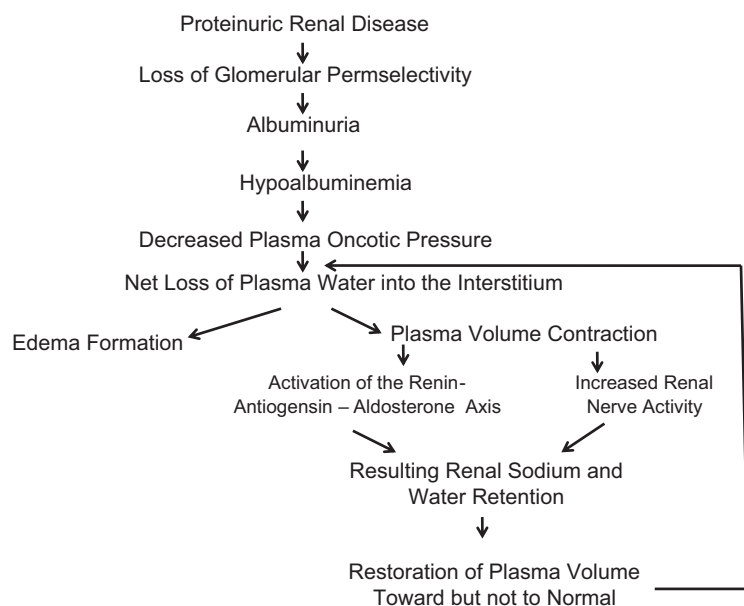

FIGURE 28.2 Primary edema formation with renal sodium retention. The plasma underfill hypothesis: hypoalbuminemia leads to increased transudation of fluid into the interstitium resulting in plasma volume contraction with secondary activation of the renin-angiotensin-aldosterone axis and subsequent renal sodium retention. Because a normal plasma volume cannot be maintained in the presence of hypoalbuminemia, a positive feedback cycle occurs. The reabsorbed salt and water also enter the interstitial space. Edema formation is a direct consequence of hypoalbuminemia, and salt and water retention is a consequence of the plasma volume contraction that results.

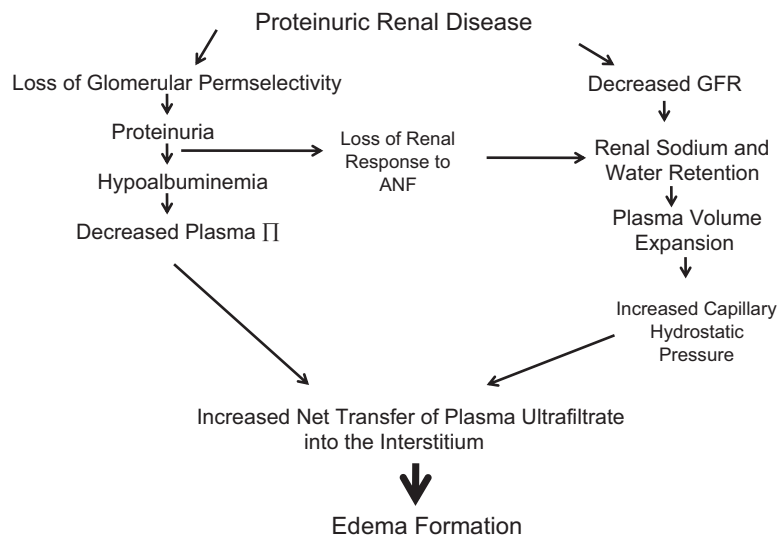

FIGURE 28.3 Primary renal sodium retention with edema formation. The plasma overfill hypothesis: renal salt and water retention occurs as a result of the renal disease or protein losses causing plasma volume expansion. This produces increased capillary hydrostatic pressure, which in conjunction with the increased transcapillary flux of fluid resulting from hypoalbuminemia, causes edema. Edema formation is not a direct consequence of reduced oncotic pressure alone. Renal salt and water retention is also a consequence of an unresponsiveness of the kidney to ANP. ANP, Atrial natriuretic peptide.

This is a consequence of proteinuria, with an increased presentation of plasma proteases, such as plasmin, as a consequence of filtration of nonalbumin biologically active proteins. ENaC is composed of three subunits: the alpha, beta, and gamma. Plasmin and aprotinin, and presumably other proteases, activate ENaC, by cleaving the alpha and gamma subunits. This offers the potential for the treatment of nonphysiologic Na reabsorption by protease inhibition.

The initial experiment that clearly demonstrated the dominant effect of proteinuria was conducted by Ichikawa et al. in an experiment where proteinuria was induced in one kidney using a puromycin model [201]. The proteinuric kidney retained salt in contrast to the nonproteinuric kidney exposed to the same plasma albumin concentration. In a second study reported by Perico et al. [202] using a unilateral model of proteinuria induced by adriamycin infusion affecting only one kidney, the proteinuric kidney had no natriuretic response to infused atrial natriuretic peptide (ANP). Additionally, plasma volume was expanded in nephrotic animals compared to controls; ANP was elevated, but the animals were still in positive sodium balance. This physiologic pattern is also observed in patients with the nephrotic syndrome [203]. Additionally, exogenous ANP administration to nephrotic patients increased urinary protein excretion leading to a positive feedback loop, where decreased responsiveness of the nephrotic nephron to ANP leads to further volume expansion with resulting increased stimulus for the secretion of ANP.

We reported that the formation of edema, measured as the volume of distribution of  $^{22}\text{Na}$ , did not increase in the absence of plasma volume expansion using a model of membranous nephropathy with anti-FX1A serum [204,205]. This model is supported by the observation that albumin infusion to normalize oncotic pressure does not result in a natriuresis [206]. Edema is, thus, a consequence of a reduction in  $\Delta\pi$  resulting in an increase in flux of fluid into the extravascular space and an increase in hydraulic pressure resulting from primary renal sodium retention. The increased fluid flux is initially counteracted by increased lymphatic return, bringing with it albumin and other proteins from the interstitial space back into the plasma compartment. This leads to the redistribution of albumin. This model of overfill edema formation would favor treatment with amiloride and/or furosemide or other loop diuretics.

A subset of patients, especially children with the nephrotic syndrome, does not fit into the model of overflow edema and clearly has evidence of hypovolemia consistent with the classic underfill model [207] in which some patients have physiologic evidence of volume depletion, such as increased plasma levels of aldosterone, renin, and norepinephrine as well as

increased hematocrit and low urinary fractional excretion of Na. Clearly this does not exclude the possibility of a combined effect of reduced oncotic pressure acting in addition to an inability of the kidney to excrete Na even if plasma volume expansion was induced. Even in patients with minimal change disease and the nephrotic syndrome, plasma and blood volumes are found to decrease when they enter remission [3], suggesting that primary renal sodium retention in these cases is the dominant mechanism (Fig. 28.3).

Additionally, there is evidence, at least in some models, that capillary permeability is increased, adding an additional mechanism to reduction in  $\Delta\pi$  and plasma volume expansion [208]. Circulating vascular permeability factors have been identified in lymphocytes or plasma from patients with some forms of the nephrotic syndrome, adding a third potential pathway responsible for the development of edema [209–212]. The treatment of edema should be targeted after some evaluation regarding the dominant mechanism responsible for edema formation in an individual patient.

Ultimately, edema occurs when the amount of fluid filtered into the interstitium exceeds maximal lymph flow, decreasing the circulatory volume due to the plasma ultrafiltrate left behind in the interstitium [213]. In the setting of the nephrotic syndrome, with the fall in plasma albumin concentration and oncotic pressure, there is a concomitant fall in interstitial oncotic pressure [214]. Thus there are probably only minor changes in the transcapillary oncotic gradient, and hypoalbuminemia is not the primary step in edema formation. In patients with minimal change disease going into remission with corticosteroid treatment, the maximum recovery diuresis occurs before there has been a substantial increase in plasma albumin concentrations [215]. Dorhout and coworkers [3] found that both plasma and blood volumes decreased in individual patients with minimal-change nephrotic syndrome when they entered remission, providing strong evidence that even (adult) patients with minimal-change nephrotic syndrome were apparently plasma volume expanded during their “nephrotic” phase. Furthermore, they found no correlation between plasma volume and renin activity, or between plasma albumin and blood volume [216]. The lack of a relationship between plasma renin activity and blood volume or between plasma albumin and blood volume is characteristic of both patients with minimal-change nephrotic syndrome and patients with other kidney diseases. The two groups were indistinguishable [216]. These observations raised important questions about the proposed mechanism of edema formation in the nephrotic syndrome.

As indicated earlier, both experimental and human studies have suggested relative resistance to ANP in

cases of the nephrotic syndrome. This defect may be due, in part, to increased phosphodiesterase activity in the nephrotic kidney leading to more rapid degradation of cyclic GMP (cGMP), which is the second messenger for ANP. Valentin et al. [217] found that the normal increase in urinary cGMP that follows saline infusion was blunted in nephrotic rats because of increased phosphodiesterase in the inner medullary collecting duct cells. Treatment with a phosphodiesterase inhibitor reverses this defect and restores the normal natriuretic response to volume expansion. Thus an increase in phosphodiesterase activity in the nephrotic syndrome was proposed to accelerate hydrolysis of cGMP resulting in impaired natriuresis. These observations provide a cellular basis for the observations of Perico et al. [202] and Ichikawa et al. [201]. The proteinuric kidney avidly reabsorbs filtered salt in the distal nephron and is not responsive to increased ANP that should normally cause a natriuresis when plasma volume is expanded [201]. In addition, there is increased activity of the sodium–potassium ATPase pump in the cortical collecting duct in nephrotic rats [218].

### The management of edema

There is no uniformly recognized treatment regimen for patients with the nephrotic syndrome. The aim of medical management is to reduce the excessive extravascular fluid that has accumulated without decreasing plasma volume below a value necessary for physiologic homeostasis. It is possible for patients with the nephrotic syndrome to become plasma volume contracted. This must be detected, guarded against, and treated. It is, however, impossible to predict the plasma volume of a nephrotic patient by measuring plasma protein or albumin concentration or by measuring plasma renin activity [216]. It is important, therefore, to estimate the intravascular volume state of each patient individually by measuring orthostatic blood pressure, observing neck vein distention, and evaluating the serum urea relative to serum creatinine. Patients who show no evidence of plasma volume contraction should respond to the gentle use of diuretics. Patients who have plasma volume contraction should not be treated with diuretics, but their volume deficit should be treated by bed rest, support hose, or even fluid replacement if necessary.

As indicated earlier, there are two factors responsible for edema in the nephrotic syndrome, and the dominant one in most patients is primary renal sodium retention due to the effect of proteinuria on the ENaC receptor system. Primary treatment beyond focusing on decreasing urinary protein losses by the use of an ACE inhibitor or an ARB as well as modest dietary protein

restriction would be dietary sodium restriction to less than 3 g/day and the use of a diuretic. The most commonly used category of diuretics is loop diuretics, such as furosemide or bumetanide [20]. These agents must be bound to albumin for delivery to the loop of Henley via secretion by organic anion transporters [219], and hypoalbuminemia may decrease their effectiveness, both by limiting their absorption in the gut and by reduced transport to the secretory sites as a consequence of low serum albumin concentrations [220]. Infusion of albumin has been used both to increase plasma volume in the event that reduction in plasma volume plays a role in an individual patient and to increase the delivery of loop diuretics, but the effects are of limited value and not recommended [221–223]. Furosemide is generally the most widely used diuretic [224], although it is less effective than bumetanide. In patients who fail to respond to loop diuretics, the most physiologically relevant second agent should be the addition of an ENaC inhibitor such as triamterene [225] or amiloride [226]. Comparison studies are too limited to make firm recommendations.

As indicated earlier, a fraction of nephrotic patients actually has reduced plasma volume as evidenced by increased hematocrit and activation of the renin–angiotensin system. Volume contraction effected by diuretics in this population could potentially increase the risk of reduction in renal perfusion or hemoconcentration which could result in renal insufficiency or thromboembolism [160]. Albumin infusions aiming to increase natriuresis by the suppression of the renin/angiotensin/aldosterone system by volume expansion has not proved to be effective [227,228]. The treatment of edema should consist of restriction of dietary sodium and addition of diuretics as described earlier.

### Recommendations for nutritional and nonnutritional treatment of the nephrotic syndrome

The treatment of the nephrotic syndrome begins with identifying the specific cause of the proteinuria and treatment of the underlying disorder, if possible. There are, however, general nutritional and nonnutritional management issues in patients with the nephrotic syndrome per se.

### The role of dietary protein modification in the management of the nephrotic syndrome

Dietary protein restriction has been proposed to reduce the rate of progression of renal disease because of the effect of dietary protein on glomerular pressure

and other physiological and structural processes [229,230]. The effect of dietary protein restriction on progressive loss of renal function, especially among subjects without significant proteinuria, was not clearly shown to be statistically significant [231,232]. However, increasing dietary protein in patients or in experimental animals with nephrotic range proteinuria has immediate significant adverse effects on proteinuria, causing increased urinary protein loss and reduced serum albumin concentration despite an increase in albumin synthetic rate [28,30]. The major rationale(s) for changing a patient's diet is to blunt manifestations of the syndrome, such as by sodium restriction to address edema and the replacement of nutrients lost in the urine, which may contribute to anemia, bone disease, and other adverse manifestations of the nephrotic syndrome. It might also be possible that specific allergens contained in food may cause renal disease in some patients [233–237]. In this case, dietary modification might prove curative.

Renal blood flow, GFR [55,238,239], and the permselective properties of the glomerular capillary [28,30,49,51] increase quickly following an augmentation in dietary protein intake. Renal hypertrophy also occurs [81,240,241]. Ingestion of protein can result in the release of a cascade of hormones and vasoactive substances, including growth hormone [54], insulin [54], glucagon [242], kinins [243], prostaglandins [50], dopamine [78,244], and insulin-like growth factor-1 [245,246]. In addition, the renin–angiotensin system has been implicated as one of the mediators of protein-induced hyperfiltration [80]. Dietary protein intake stimulates renin secretion [49], and the secondary formation of angiotensin II will, by its effect on efferent arteriolar vasoconstriction, increase intraglomerular capillary pressure and GFR [69].

Proteinuria is responsible for all the manifestations of the nephrotic syndrome: reduced plasma oncotic pressure, edema formation, hyperlipidemia, loss of divalent cations, and anemia. Proteinuria also plays a causative role in the loss of renal function, adding to the effects of the underlying disease that caused the defect in glomerular permselectivity that resulted in the nephrotic syndrome. All therapy must be directed to decrease urinary protein losses. Replacement of urinary protein loss by increasing dietary protein leads to an increase in glomerular permselectivity, which further increases urinary protein losses, primarily by increasing glomerular protein clearance. The net result is a further decline in serum albumin levels [28,30,247] and likely an increase in renal injury mediated by the filtered proteins. Dietary protein should be reduced. Although the absolute target has not been defined, a diet containing 0.8 g/kg/day seems to be a safe target. Clearly high-protein diets are injurious. Pharmacologic intervention should be focused

on the inhibition of the renin–angiotensin system by the administration of ACE and/or ARBs [248–250]. Reducing proteinuria decreases a stimulus for renal fibrosis [251] and loss of renal function [252]. Reduction in proteinuria also should reduce serum lipid levels as well as the stimulus for renal salt reabsorption that contributes to edema formation.

ACE inhibitors [172,173] or angiotensin II receptor antagonists have become the mainstay of treatment as a result of evidence from randomized controlled trials and metaanalyses [47,253]. Aldosterone receptor antagonists also reduce proteinuria [254,255]. The effect of spironolactone administration in patients with persistent proteinuria on long-term angiotensin-converting enzyme inhibitor therapy with or without an angiotensin II receptor blocker was investigated in a double-blind, placebo-controlled study. A significant reduction in proteinuria was observed among patients given spironolactone [256]. In another study, Tylicki et al. showed that an aldosterone receptor antagonist in addition to double renin–angiotensin blockade was able to reduce proteinuria and slow the progression of the disease in nondiabetic patients with CKD [257]. In an acute animal model of the nephrotic syndrome, Fukuda et al. showed that blockers of mineralocorticoid receptors and angiotensin II receptors decreased proteinuria and preserved expression of glomerular podocyte protein independently of blood pressure levels [255].

Thus proteinuria can be ameliorated with the use of blockers of the renin–angiotensin–aldosterone system without modification in blood pressure. Treatment with combinations of these blockers reduces proteinuria more effectively than a single drug alone. The use of these agents must be associated with regular monitoring of serum electrolytes, particularly serum potassium, which may increase to hazardous levels, and sodium levels, which may decrease with the use of diuretics. The full antiproteinuric effect of these blockers can take several months to become evident. Independently of these blockers, blood pressure lowering will also reduce proteinuria.

C-C chemokine receptor type 2 has recently been implicated in mediating renal injury and fibrosis associated with proteinuria [258], and blockade of this receptor has been shown to reduce both proteinuria and associated renal fibrosis [259,260], providing an additional pharmacologic target.

## Hyperlipidemia

Nephrotic syndrome results in hyperlipidemia and important modifications in lipoprotein and lipid metabolism [261]. Hyperlipidemia in the nephrotic syndrome poses the danger of accelerated atherosclerosis and progressive renal injury. Reduction in plasma lipid levels

has been accomplished using such therapies as a low-fat diet [102] and fish oil supplements [175]. Dietary therapy with a low-fat diet, however, is generally of only minimal benefit, and there is no long-term experience with the use of a low-fat diet in the treatment of the hyperlipidemia of the nephrotic syndrome. In addition, there is no compelling reason to prescribe unsaturated fatty acid supplements (such as fish oil) until robust data from randomized controlled studies are available. The general recommendation is to ingest a diet low in cholesterol and saturated fatty acids. It has been shown that reducing proteinuria, using drugs such as ACE inhibitors, lowers blood lipid levels in nephrotic animals [138] and humans [262]. Keilani et al. [262] demonstrated a 10%–20% decrease in the plasma levels of total cholesterol and LDL-cholesterol and Lp(a) with the use of an ACE inhibitor. The magnitude of these changes appears to be related to the degree of reduction in proteinuria. The angiotensin II receptor antagonist, losartan, appears to have a similar beneficial effect on the lipid profile in nephrotic patients [263]. Thus therapy directed at reducing the increased renal clearance of macromolecules has a salutary effect on improving the hyperlipidemia associated with the nephrotic syndrome.

The changes in the metabolism and serum levels of lipoproteins in the nephrotic syndrome are associated with the development and progression of kidney disease and cardiovascular complications [264]. Also, by limiting the lipid flow to muscle to provide energy and to the adipose tissue for energy storage, modifications in the lipid profile may affect the body mass and altered exercise capacity [261].

A study conducted on patients with idiopathic nephrotic syndrome showed that the addition of 20 mg/day of fluvastatin to the basic therapy was associated with a 40% reduction in serum cholesterol levels, a 60% reduction in proteinuria, and a 60% increase in serum albumin levels [265]. Similar results were obtained by Valdivieso et al. after administering 10 mg/day of atorvastatin to 10 dyslipidemic patients who had hypoalbuminemia and proteinuria greater than 3.5 g/24 h [266]. Rayner et al. [264] showed that, in patients with the nephrotic syndrome, the use of a low-lipid diet without pharmaceutical treatment led to a minimal reduction in plasma cholesterol levels, a limited reduction in urinary protein excretion, and normalization of serum albumin levels. Lipid-lowering agents, such as statins [267], probucol [268,269], or gemfibrozil [270], may prove useful in reducing blood lipid levels in these patients [271–273]. The long-term benefits of treatment remain unproven but may include a reduction in cardiovascular risk and preservation of residual renal function. Use of these agents may engender some morbidity, such as rhabdomyolysis with statins [274],

especially when given in combination with gemfibrozil [275], and also hepatotoxicity.

It is noteworthy that many nephrotic patients go into remission with the treatment of the underlying disease. Thus identifying and treating the underlying cause of nephrotic syndrome and thereby reducing proteinuria will improve or resolve the dyslipidemia.

## Antioxidants

Increased levels of oxidative stress markers have been found in sera and urine of nephrotic children [181] and in animal models of the nephrotic syndrome [276,277]. In children, it was shown that primary nephrotic syndrome is associated with oxidative stress even during remission. This stress may modulate the response to corticosteroids [278]. Pedraza-Chaverri et al. showed that proteinuria, hypoproteinemia, renal dysfunction, and ultrastructural alterations were higher in nephrotic rats fed a deficient diet of antioxidants in contrast to rats treated with vitamin E and selenium [279]. In other studies, after the treatment of nephrotic animals with such antioxidants as catalase or  $\alpha$ -tocopherol, a significant reduction of the proteinuria was observed [280–282]. Granqvist et al. described an increase in the plasma antioxidant capacity combined with decreased oxidation of proteins in sera from nephrotic rats [283]. This observation suggests that oxidative damage to glomerular cells may contribute to the progressive renal injury in the nephrotic syndrome [283]. Recently, Sutariya et al. found that a natural bioactive compound named  $\alpha$ -asarone, which has been shown to have protective properties against doxorubicin-induced nephrotic syndrome, when administered in an animal model of nephrotic syndrome, restored antioxidant enzyme activities in kidney tissue [284]. These data should be considered preliminary, and we expect more information from future experimental studies.

In conclusion, the use of antioxidant medicines in the nephrotic syndrome appears useful, but large clinical trials to ascertain their effectiveness and safety in nephrotic patients are still lacking.

## Introduction

Chronic kidney disease (CKD) is closely related to nutritional status and diet [1]. Altered protein and energy homeostasis, abnormal protein catabolism, acid–base derangements, and hormonal dysfunction all affect the nutritional status of patients with kidney disease. In children, growth and development are hindered [2]. Accumulation of nitrogen-containing products from dietary and intrinsic protein catabolism may distort taste and smell and blunt appetite [2]. Nutrient absorption through the gastrointestinal (GI) tract becomes abnormal, as uremia affects the microbiome and disrupts intestinal epithelia [3]. Muscle and fat wasting often develop, exacerbated by the comorbid conditions and frailty inherent to the advanced age of many CKD patients. Hence, nutritional status often becomes disordered, and protein-energy wasting (PEW) is common, justifying the need for dietary adjustments in this population. Nutritional therapy may help manage uremia, as well as other complications such as electrolyte and acid–base imbalances, fluid and salt retention, mineral and bone disorders, and failure to thrive. Dietary interventions may also be used for the conservative management of uremia when the transition to

dialysis needs to be delayed or avoided. It is possible, though not yet unequivocally proven, that such nutritional interventions may also slow the rate of disease progression, independent of uremia management. Given that approximately 10% of the adult population globally has CKD [4], and considering the exceptionally high costs of maintenance dialysis therapy and kidney transplantation, supportive management of CKD via dietary interventions may offer a feasible and economical alternative.

## Dietary protein in kidney disease

It is unclear whether quantity or quality of ingested protein is a risk factor for incident kidney disease. Evidence suggests that daily dietary protein intake (DPI) exceeding 1.5 g/kg of ideal body weight (g/kg/d) may cause glomerular hyperfiltration [5] and proinflammatory gene expression [6], both known risk factors for kidney disease, as in the diabetic nephropathy model [7]. A high-protein diet exacerbates proteinuria in persons with diabetes or hypertension [8], but as a popular weight reduction strategy its net effect on kidney health is unclear.

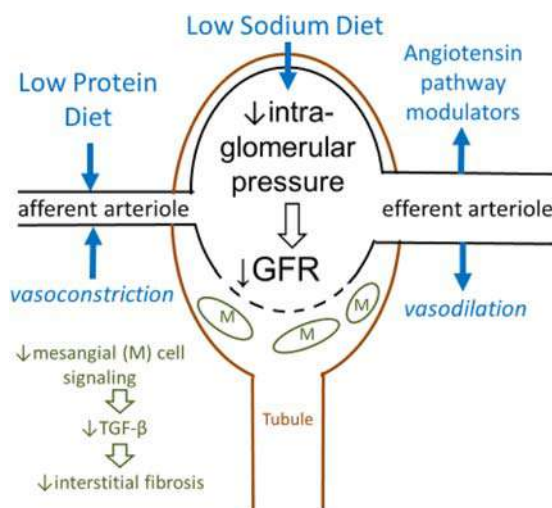

Animal models have consistently demonstrated that low protein intake constricts the glomerular *afferent* arterioles, whereas they dilate in nephropathies as a compensatory mechanism to rise intraglomerular pressure, which increases glomerular filtration [9]. Over time, the glomerular hyperfiltration damages the remaining glomeruli [6]. Thus a low-protein diet (LPD) has a preglomerular effect that can enhance the post-glomerular effect of angiotensin pathway modulators that lower intraglomerular pressure by dilating the *efferent* arterioles (Fig. 29.1) [11]. Human studies of dietary protein restriction, however, have been less consistent. The *Modification of Diet in Renal Diseases* (MDRD) study reported that the progression of kidney disease was only minimally decelerated by an LPD [12]. Several limitations of the MDRD study should be noted [13]. Most other controlled trials have confirmed

beneficial effects of restricted protein intake as did several metaanalyses that included the MDRD study [14].

Current evidence suggests that an LPD mitigates proteinuria in both experimental [5] and human kidney disease models [15]. The proteinuria amelioration is likely related to the reduction in intraglomerular pressure (Fig. 29.1) [11]. This favorable effect is independent of angiotensin pathway modulation [11] and holds even in nephrotic ranges of proteinuria [16] and in earlier stages prior to the development of renal insufficiency, particularly if the patient was previously consuming a high-protein diet [11,17].

Restricting dietary protein also results in a proportional reduction in urea generation [18]. After breakdown of protein, individual amino acids are deaminated by the removal of an  $\alpha$ -amino group, leaving a carbon skeleton ketoacids, which can be recycled to form other amino acids and proteins or can be used for energy generation via the tricarboxylic acid cycle [19], while urea is generated through the urea cycle (Fig. 29.2). Persistently high blood urea concentrations, called *azotemia*, a commonly used marker for *uremia*, may enhance protein carbamylation and generate reactive oxygen species leading to oxidative stress, inflammation, endothelial dysfunction, and cardiovascular (CV) disease [20]. This process is decreased by decreasing protein intake in the diet. Ameliorating azotemia by eating less protein results in parallel reductions of other nitrogenous compounds that act as putative uremic toxins [21]. Although uremic symptoms diminish by eating less protein, there are limited studies that have examined the effectiveness and safety of the LPD as a means to defer or avoid transition to dialysis therapy [22,23].

Among different ranges of low protein intake the 0.6–0.8 g/kg/d range is the most frequently recommended target for patients with moderate-to-advanced kidney disease [estimated glomerular filtration rate (eGFR) <45 mL/min/1.73 m<sup>2</sup>] and for the management of substantial proteinuria (>0.3 g/d), whereas the so-called very LPD (<0.6 g/kg/d) supplemented with essential amino acids or their ketoacids is also used [24]. People at higher risk of kidney disease such as those after donor or cancer nephrectomy, diabetes mellitus, or hypertension may benefit from a modest protein intake of <1 g/kg/d to maintain a moderately low intraglomerular pressure [25]. Safety and feasibility of low protein intake, risk of PEW, and patient adherence to dietary restrictions are among the main concerns (Table 29.1) [26]. The *recommended dietary allowance* (RDA) for protein is 0.8 g/kg/d, while 0.66 g/kg/d is the *estimated average requirement* for otherwise healthy adults; hence, a diet consisting of 0.6–0.8 g/kg/d fulfills dietary needs. Clinical trials of LPD s administered at the lower threshold (0.6 g/kg/

**FIGURE 29.1** The effects of a low-protein and low-salt diet on afferent arteriole contraction leading to reduced intraglomerular pressure. By contracting the afferent arteriole and lowering intraglomerular pressure, a low-protein diet results in incrementally lowered GFR, but in the long term it diminishes the damage to the glomerulus structure and function. A potential secondary effect of lowered intraglomerular pressure is mitigated mesangial (M) cell signaling leading to lower TGF- $\beta$  expression and reduced interstitial fibrosis. These renoprotective effects of a low-protein diet can be synergistic with the direct effect of low-sodium diet as well as the effect of angiotensin pathway modulators (angiotensin converting enzyme inhibitors and angiotensin receptor blocker agents) in dilating the efferent arteriole and thereby more effectively reducing intraglomerular pressure and glomerular damage. On the contrary, a high-protein diet dilates *afferent* arteriole and elevates intraglomerular pressure leading to increased GFR in short term, while the glomerular hyperfiltration stimulates M cell signaling leading to increased TGF- $\beta$  release and subsequent progressive fibrosis and renal damage in long term. GFR, Glomerular filtration rate. Source: Adapted from Ko GJ, Rhee CM, Kalantar-Zadeh K, Joshi S. The effects of high-protein diets on kidney health and longevity. *J Am Soc Nephrol* 2020;31(8):1667–79. <https://doi.org/10.1681/ASN.2020010028>. PubMed PMID: 32669325; PMCID: PMC7460905. <https://www.ncbi.nlm.nih.gov/pubmed/32669325> [10].

**FIGURE 29.2** Relevant metabolic pathways related to protein and amino acid metabolism in chronic kidney disease. The TCA relates to a series of chemical reactions that can metabolize amino acids. Amino groups are the products of amino acid deamination. Urea is synthesized through the urea cycle in the liver from the oxidation of amino acids or from ammonia. These mechanisms serve to trap and neutralize the highly volatile and toxic ammonia that is released from  $\alpha$ -amino groups upon the transamination of amino acids in the liver. *Acetyl-CoA*, Acetyl coenzyme A; *Ca*, calcium; *FGF-23*, fibroblast growth factor 23; *HTN*, hypertension; *NH<sub>3</sub>*, ammonia; *NH<sub>4</sub><sup>+</sup>*, ammonium; *phos.*, phosphorus; *PTH*, parathyroid hormone; *ROS*, reactive oxygen species; *TCA*, tricarboxylic acid; *Trp*, tryptophan; *Tyr*, tyrosine; *vascular dys.*, vascular dysfunction; *α-ketoglu.*,  $\alpha$ -ketoglutaric acid.

d) or even less such as the MDRD study have rarely, if ever, reported deterioration of nutritional status [12,26]. However, in most children as well as in adults at higher risk of malnutrition, higher protein intake closer to 0.8 g/kg/d may be necessary to assure appropriate growth and development and to prevent or correct PEW. The safety and adherence to an LPD can be improved by provision of adequate energy of 30–35 Cal/kg/d and ongoing nutritional education and surveillance [27,28].

### High-protein diets may be harmful to kidney health

While the United States National Academy of Medicine has maintained that RDA of DPI should be 0.8 g/kg of the ideal body weight per day (g/kg/d), Americans on average consume much higher amounts of protein, that is, 1.2–1.4 g/kg/d, mostly from animal sources, according to analyses from the National Health and Nutrition Examination Survey (NHANES) [29]. In recent practice, higher DPI has been recommended to combat obesity and diabetes [30,31], despite

recent data suggesting higher risk of CKD incidence and progression with higher DPI, especially from red meat [32–34]. Ketogenic (keto)-diets, which are also high in protein and animal fats, are gaining popularity across different health-care systems throughout the world as a recommended dietary intervention for adults with diabetes [35]. Despite its immediate appeal for the use of type 2 diabetes, the keto-diet has not been as effective for glycemic control or weight loss in randomized, controlled trials as often touted and may carry additional risks to long-term health [36]. Further, previous and emerging data suggest that high DPI in these diets, by the way of causing increased intraglomerular pressure with resultant glomerular hyperfiltration, may adversely affect kidney health over time across populations with or at-risk for CKD [10,32].

### An LPD preserves kidney function

The scientific premise for low DPI targets was presented in a recent critical review and metaanalysis of 16 dietary trials with more than 30 CKD patients in each trial (Fig. 29.3) [37] and also discussed in a 2017

**TABLE 29.1** Potential benefits and challenges of a 0.6–0.8 g/kg/d low-protein diet (LPD) in the nutritional management of chronic kidney disease (CKD)<sup>a</sup>.

	Potential benefits	Challenges and risks	Additional comments
CKD progression	Synergistic effect with angiotensin pathway modulators <sup>b</sup> to lower intraglomerular pressure	In the first several months a slight drop in GFR may be observed as shown in the MDRD study <sup>c</sup>	Inconclusive results in the MDRD study, but a small effect size in metaanalyses <sup>d</sup>
Effect on proteinuria	Consistent antiproteinuric effect may improve hypoalbuminemia	Contrary to the notion that a higher DPI is needed to replace urinary protein loss	Some data suggest that even larger effect may be achieved by DPI of <0.6 g/kg/d
Uremia management and deferral of dialysis initiation	Consistent and biologically plausible data for almost a century	Unlikely to worsen uremia but potential risk of resurfacing or exacerbating PEW	Patients at higher risk of PEW may benefit from supplements, including EAA or KA
Metabolic acidosis	Lower H <sup>+</sup> generation is proportional to less DPI, especially with larger vegetarian food proportion	The need for >50% HBV may prompt higher nonvegetarian foods that are more acidogenic	While >50% HBV protein is recommended, the remainder can be plant-based foods
Mineral and bone disease	Inherently lower phosphorus content of LPD improves mineral bone disease parameters, including sHPT and high FGF-23	Higher calcium content in some KA preparations may worsen calcium loads	Additional improvements in bone health by alleviating acidosis can be achieved
PEW	Improving hypoalbuminemia in proteinuric patients may help neutralize circulating inflammatory compounds	Weight loss may occur. LPD-intake patterns may continue following thrice-weekly hemodialysis therapy when higher protein intake is recommended	Use HBV as 50% of the source of dietary protein. Liberalize diet during PEW correction episodes (see Table 29.2)
Cardiovascular and metabolic health	Lower protein intake is associated with lower dietary salt and potassium and may be less atherogenic given higher proportion of vegetarian food	Higher dietary fat intake (to achieve DEI 30–35 Cal/kg/d) may confound the goal of achieving a heart-healthy diet profile	Higher proportions of unsaturated fat and complex carbohydrates are recommended (see Table 29.2 and text)
Glycemic control and insulin response	Improvement in insulin resistance is likely	Higher carbohydrate and fat intake (to achieve DEI >30–35 Cal/kg/d) may worsen glycemic control in LPD or VLPD	Given increased insulin-half-life and burnt-out diabetes with CKD progression, preventing hypoglycemic episodes are prudent
Quality of life and adherence	High degree of patient centeredness given that many CKD patients proactively seek nutritional therapies and dietary advice	Challenges with adherence, diet fatigue, poor palatability, and cravings are reported	Recommend creative recipes and strategies to engage patients
Mortality	No convincing data to suggest improved survival, although dialysis therapy deferral is a potential mechanism given high early dialysis death	Highly unlikely to cause higher death risk with DPI 0.6–0.8 g/kg/d unless severe PEW emerge and remain uncorrected	Consider supplements or other corrective strategies whenever PEW is suspected or diagnosed
Hypertension management	MDRD and other data suggest improved BP control	Less likely to increase BP given inherently lower salt intake	Lower salt intake may be a potential mechanism
Microbiome modulation	Improved microbiome profile may be achieved by less uremic toxin generation	Less likely to promote an unfavorable microbiome milieu	Uremia per se can lead to an unfavorable microbiome

<sup>a</sup>See examples of meals/recipes based on the suggested ranges and recommendations.<sup>b</sup>Angiotensin pathway modulators include ACE inhibitors and ARB.<sup>c</sup>The MDRD study data were originally presented by Klahr et al. [12] with additional analyses by Levey et al. [13].<sup>d</sup>Metaanalyses by Kasiske et al. show a statistically significant but rather small effect size of LPD in slowing the CKD progression rate [14].

*New England Journal of Medicine* review paper [1]. These data highlight the utility of LPD for the management of CKD (Table 29.2), suggesting that an LPD of 0.6–0.8 g/kg/d versus higher amounts is associated

with lower ESKD risk, higher serum bicarbonate and lower serum phosphorus levels, less azotemia, and lower mortality trends [37]. Whereas we and others have recommended DPI of 0.6–0.8 g/kg/d, some other

investigators, including Metzger et al. [53], showed that a DPI of  $<0.6$  g/kg/d may result in even slower CKD progression; however, a DPI of  $0.6$ – $0.8$  g/kg/d is considered the most pragmatic and safest target when used without amino acid or keto-analog supplements to avoid PEW. For persons without established CKD but who are at a high risk of CKD, such as those with a solitary kidney or diabetic glomerular hyperfiltration, it is recommended that a high DPI  $>1.0$  g/kg/d should be avoided [54], especially since patients with diabetes develop more severe hyperfiltration in response to high DPI [55].

### Plant-based foods have a favorable impact on kidney health

The typical American diet contains 15%–20% protein with less than one-third of protein sources from plants [56]. While human trials on the effects of high protein intake have yield mixed findings, animal models are relatively consistent with evidence of histological damage, including a 60%–70% increase in renal and glomerular volumes, 55% more fibrosis, and 30% more glomerulosclerosis [57]. A recent comprehensive and critical review of the literature concluded that daily red meat consumption over years may increase CKD risk, whereas fruit and

vegetable proteins may be renal protective [33]. Prior studies summarized by some of the authors of this article [54,58–62] and others [63–66] suggest that animal-based protein is harmful to kidney health, while a plant-dominant diet may slow CKD progression. A landmark study was presented by Kontessis et al. [67] who studied volunteers fed for 3 weeks with a vegetable-based diet ( $N = 10$ ), an animal protein diet ( $N = 10$ ), or an animal protein diet supplemented with fiber ( $N = 7$ ), all with the same amount of total protein; animal-based protein diets increased glomerular filtration rate (GFR) more than similar amounts of plant-based proteins, that is, higher glomerular hyperfiltration was observed with more meat and less vegetable-derived proteins [67]. Other important studies supporting the benefit of a plant-dominant diet in slowing CKD progression include the study by Lin et al. [68] (examined 3348 women in the Nurses' Health Study and found that the highest quartile of meat intake was associated with 72% higher risk of microalbuminuria), Kim et al. [69] (showed that in 14,686 middle-aged adults, higher adherence to a plant-based diet was associated with favorable kidney outcomes), Haring et al. [70] (showed that red and processed meat were associated with higher CKD risk, while nuts, low-fat dairy products, and legumes were protective against the development of CKD), and Chen et al. [71] (showed lower mortality in CKD patients on diet with higher plant sources).

### Benefits of a plant-dominant LPD

We have defined a plant-dominant LPD, also referred to as PLADO, as a type of LPD with DPI of  $0.6$ – $0.8$  g/kg/d with at least 50% plant-based sources to meet the targeted dietary protein, and which should preferably be whole, unrefined, and unprocessed foods (Fig. 29.4) [72]. This is consistent with the RDA of DPI of  $0.8$  g/kg/d, which has a high safety margin, given that based on established metabolic studies [73] the lowest DPI requirement to avoid catabolic changes is  $0.45$ – $0.5$  g/kg/d. It has been previously suggested that  $\geq 50\%$  of DPI should be of “high biologic value” with high GI absorbability to ensure adequate intake of essential amino acids while on LPD [74]. However, other metrics, including the “protein digestibility-corrected amino-acid score,” which is a more accurate method recommended by the Food and Agricultural Organization and the World Health Organization, grant high scores to many plant-based sources and may be a more appropriate measure of protein quality [75]. Other features of PLADO include relatively low sodium intake  $<3$  g/d, higher dietary fiber of at least  $25$ – $30$  g/d, and adequate dietary energy intake (DEI)

TABLE 29.2 Low-protein diet (LPD) controlled trials with greater than 30 participants in each study [1].

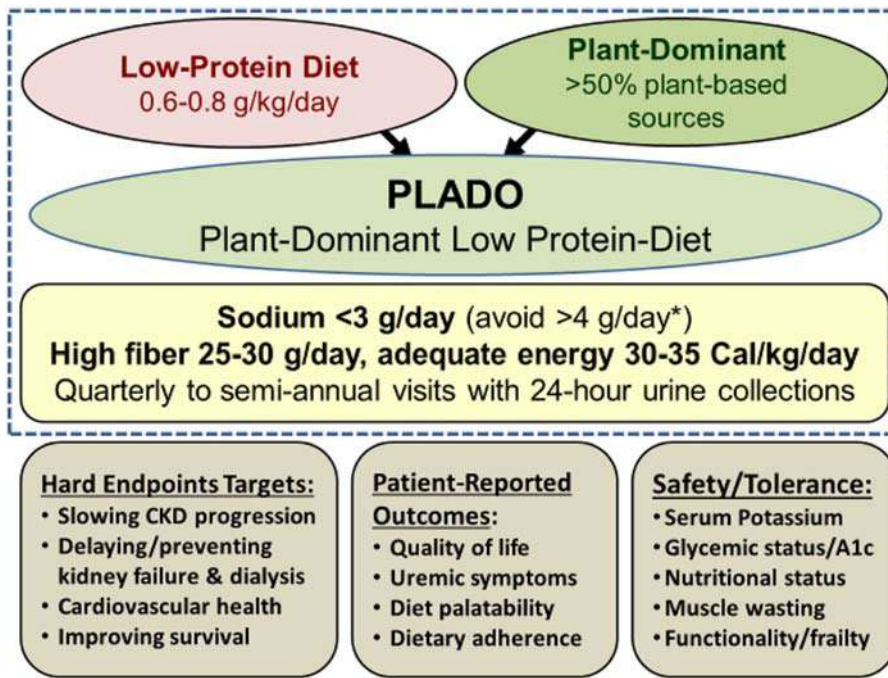

Reference	Participants	Diet (g/kg/d)	Duration of follow up	Results
Rosman [38,39]	247 CKD 3–5 pts	0.90–0.95 versus 0.70–0.80 versus unrestricted	4 yrs	Significant CKD slowing in LPD in male pts
Ihle [40]	72 CKD 4–5 pts	LPD (0.6) versus higher DPI (0.8)	18 mo	Loss of GFR in control versus LPD ( $P < .05$ ). Wt loss
Lindenau [41]	40 CKD 5 pts	LPD versus sVLPD (0.4) w KA	12 mo	Decreased phos. with sVLPD and improved bone health
Williams [42]	95 CKD 4–5 pts	LPD (0.7) versus 1.02–1.14	18 mo	No differences, minor Wt loss
Locatelli [43]	456 CKD 3–4 pts	0.78 versus 0.9	2 yrs	Trend for difference in renal outcomes ( $P = .059$ )
MDRD Klahr [12]	585 CKD 3–4 pts	1.3 versus 0.6	27 mo	No difference in GFR decline at 3 years
Montes-Delgado [44]	33 CKD 3–5 pts	LPD versus suppl. LPD	6 mo	Slower eGFR decline with supplements
Malvy [45]	50 CKD 4–5 pts	sVLPD (0.3) KA versus LPD (0.65)	3 yrs	Decreased SUN lean body mass and fat in sVLPD
Teplan [46]	105 CKD 3b–4 pts	LPD w versus w/o KA	3 yrs	Slower CKD progression
Prakash [47]	34 CKD 3b–4 pts	0.6 versus 0.3 w KA	9 mo	Faster decline in LPD
Brunori [23]	56 >70 yrs old CKD 5 pts	sVLPD (0.30) w KA versus dialysis	27 mo	Similar survival but more hospitalizations in dialysis
Mircescu [48]	53 CKD 4–5 pts	sVLPD (0.3) vegan w KA versus LPD	48 wks	Less dialysis initiation in sVLPD
Cianciaruso [49]	423 CKD 4–5 pts	0.55 versus 0.80	18 mo	Reduced urinary urea, Na, phos
Di Iorio [50]	32 CKD w proteinuria	VLPD versus LPD	6 mo	58% greater reduction in proteinuria
Jiang [51,52]	60 PD w RKF	LPD versus sLPD w KA versus HPD	12 mo	RKF decreased in the LPD and HPD
Garneata [24]	207 CKD 4–5 pts	LPD (0.6) versus sVLPD w KA	15 mo	Less dialysis initiation

CKD, Chronic kidney disease; DPI, dietary protein intake; eGFR, estimated glomerular filtration rate; KA, ketoacids (keto-analogs of amino acids); mo, months; phos., phosphorus; pts, patients; SUN, serum urea nitrogen; sVLPD, supplemented VLPD; VLPD, very low protein diet; Wt, weight; yrs, years.

of 30–35 Cal/kg/d, assuming that the DEI calculations are based on the ideal body weight, similar to the approach to calculating DPI (Fig. 29.4).

There are multiple pathways by which an LPD with at least 50% plant-based protein sources ameliorates CKD progression, in addition to reducing glomerular hyperfiltration [58] (Table 29.3):

1. Reduction in nitrogenous compounds leads to less production of ammonia and uremic toxins as an effective strategy in controlling uremia and delaying dialysis initiation [37].
2. Synergism with renin–angiotensin–aldosterone system and SGLT2 inhibitors, since LPD reinforces the pharmaco-therapeutic effect of lowering intraglomerular pressure through complementary mechanisms (Fig. 29.1) [76].
3. Attenuation of metabolites derived from gut bacteria that are linked with CKD and CV disease: Animal protein ingredients, including choline and carnitine, are converted by gut flora into trimethylamine (TMA) and TMA N-oxide (TMAO) that are associated with atherosclerosis, renal fibrosis [77], and increased risk of CV disease and death [78]. The favorable impact on the gut microbiome [79] similarly leads to lower levels of other uremic toxins such as indoxyl sulfate and *p*-cresol sulfate [80].
4. Decreased acid load: Plant foods have a lower acidogenicity in contrast to animal foods, and this alkalization may have additional effects beyond mere intake of natural alkali [81].
5. Reduced phosphorus burden: There is less absorbable phosphorus in plant-based proteins

**FIGURE 29.4** Overview of the PLADO for nutritional management of CKD, based on a total dietary intake of 0.6–0.8 g/kg/d with >50% plant-based sources, preferentially unprocessed foods, relatively low dietary sodium intake <3 g/d (but the patient can target to avoid >4 g/d if no edema with well-controlled hypertension), higher dietary fiber of at least 25–30 g/d, and adequate dietary energy intake of 30–35 Cal/kg/d. Weight is based on the ideal body weight. Note that serum B12 should be monitored after 3 years of vegan dieting. CKD, Chronic kidney disease; PLADO, plant-dominant low-protein diet. - given the presence of indigestible phytate binding to plant-based phosphorus. Fruits and vegetables are less likely to have added phosphorus-based preservatives that are often used for meat processing [64,82–84].
6. Modulation of advanced glycation end (AGE) products: Higher dietary fiber intake results in a favorable modulation of AGE [85] which can slow CKD progression [86], enhance GI motility, and lower the likelihood of constipation that is a likely contributor to hyperkalemia.
  7. Favorable effects on potassium metabolism: A plant-based diet based on more whole fruits and vegetables lessens the likelihood of potassium-based additives that are often found in meat products [87,88].

8. Antiinflammatory and antioxidant effects: There is a decreased risk of CKD progression and CV disease due to higher intake of natural antiinflammatory and antioxidant ingredients, including carotenoids, tocopherols, and ascorbic acid [89,90].

### Features of PLADO regimens

As stated earlier, the plant-dominant restricted protein diet consists of an LPD amounting to 0.6–0.8 g/kg/d with at least 50% of the dietary protein being from plant-based sources. Table 29.4 compares PLADO with a standard diet in the United States, in that the total amount and proportion of plant-based protein is usually 1.2–1.4 g/kg/d and 20%–30%, respectively, whereas the

TABLE 29.4 Comparing low-protein diet (LPD) &gt;50% plant-based protein sources.

Protein metric	Standard diet	LPD >50% plant-based sources (PLADO)
Proportion of plant-based protein (%)	20%–30%	50%–70% <sup>a</sup>
Total protein per kg IBW (g/kg/d)	> 0.8, usually 1.2–1.4	0.6–0.8
Total protein intake (g/d)	96–112 g	48–64 g
Protein density (g/100 Cal)	4.4–5.1	2.2–2.9
Proportion of energy from protein (%)	16%–19%	8%–11%
Total plant-based protein (g/d)	24–34	24–45
Total animal-based protein (g/d)	68–83	14–32 (or none <sup>a</sup> )

<sup>a</sup>Up to 100% vegan is allowed based on patient choice.

Known as PLADO versus standard diet, based on 2400 Cal/d in an 80-kg person.

PLADO not only has less total protein of 0.6–0.8 g/kg/d but it also includes 50%–70% of plant-based sources for this restricted DPI goal. Hence, an 80-kg person with CKD, for instance, would be recommended to have 46–64 g of DPI per day, out of which 24–45 g will be from plant-based sources, while the rest is according to patient choice and preferences. As shown in Table 29.4, the total amount of animal-based protein under PLADO regimen is 14–32 g/d, which is less than half of the 68–83 g/d in the standard diet, but the patient also has the choice of being nearly or totally plant-based. There are different types of vegetarian diets [58]: (1) vegan, or strict vegetarian (100% plant-based), diets that not only exclude meat, poultry, and seafood but also eggs and dairy products; (2) lacto- and/or ovo-vegetarian diets that may include dairy products and/or eggs; (3) pesco-vegetarian diets that include a vegetarian diet combined with occasional intake of some or all types of seafoods, mostly fish; and (4) flexitarians, which is mostly vegetarian of any of the previous types with occasional inclusion of meat. The PLADO does NOT require adherence to any of these strict diets, but is a flexible LPD of 0.6–0.8 g/kg/d range with 50% or more plant-based sources of protein based on the patient's choice (Table 29.4). Whereas some nephrologists may promote a pesco–lacto–ovo-vegetarian LPD with >50% plant sources, patients have the ultimate discretion to decide about the non-plant-based portion of the protein ad lib. Based on our decades-old experience in running LPD clinics, most CKD patients will adhere to 50%–70% plant-based sources, while some may choose >70% or strictly plant-based diets.

### Safety and adequacy of a PLADO

Potential challenges of PLADO are outlined in Table 29.3, which will be largely related to the adequacy and safety of this type of dietary management of CKD patients. The risks of PEW and sarcopenia are

the leading concerns, although there is little evidence for these sequelae. As discussed earlier and based on the US-recommended RDA for safe DPI ranges, it is highly unlikely that the targeted DPI of 0.6–0.8 g/kg/d with >50% plant sources will engender PEW in clinically stable individuals. No PEW was reported in 16 LPD trials cited earlier [37,73], including the MDRD trial [73], although PEW per se is a risk of poor CKD outcomes, including faster CKD progression [91]. However, it is prudent that in patients who may develop signs of PEW or acute kidney injury (AKI), higher DPI targets should be temporarily used until PEW or AKI is resolved. On the other hand, if there is concern related to the likelihood of obesity and hyperglycemia, patients and providers should be reassured that LPD therapy in CKD has not been shown to be associated with such risks, and indeed an LPD with plant-based sources has salutary effects on insulin resistance and glycemic index, as long as total calorie intake remains within the targeted range of 30–35 kcal/kg/d [59,60].

Another frequently stated concern is the perceived risk of hyperkalemia. We are not aware of scientific evidence to support the cultural dogma that dietary potassium restriction in CKD improves outcomes [92]. Evidence suggests that dietary potassium, particularly from whole-, plant-based foods, does not correlate closely with serum potassium variability [93,94]. Indeed, a high-fiber diet enhances bowel motility and likely prevents higher potassium absorption, and alkalinization with plant-based dietary sources also lowers the risk of hyperkalemia [95–99]. Of note, dried-fruit, juices, smoothies, and sauces of fruits and vegetables require additional consideration given their high potassium concentrations. Moreover, newly available potassium binders, which were not FDA-approved during the era of prior LPD trials such as the MDRD, may be used in the contemporary management of CKD patients at the discretion of clinicians [100].

Diet palatability and adherence to LPD or meatless diets are often cited as dietary management challenges. Based on our extensive experience in running patient-centered LPD clinics for hundreds of CKD patients [74], and given prior data on dietary adherence research [74,101], the suggested PLADO with DPI of 0.6–0.8 g/kg/d and >50% plant-based sources is feasible and well accepted among patients with CKD [74]. Patients have the opportunity to choose the contribution of protein plant sources between 50% and 75% or >75%, and these two strata along with palatability, appetite [102], and adherence should be monitored closely in CKD clinics. Concerns about B12 deficiency associated with meatless diets can be mitigated by the use of oral supplements as needed [103].

### **Impact of PLADO on microbiome in CKD**

Eating a plant-dominant, fiber-rich LPD may lead to favorable alterations in the gut microbiome, which can modulate uremic toxin generation and slow CKD progression, along with reducing CV risk in CKD patients [1,104–106]. Uremic plasma impairs barrier function and depletes the tight junction protein constituents of intestinal epithelium [107]. The influx of retained uremic solutes from the bloodstream per se induces changes in the microbial population simultaneously with gut wall inflammation and breakdown of epithelial junctions [108–119]. Bacteria-derived toxins then translocate back across the leaky gut barrier into the systemic circulation and promote inflammation and multiorgan dysfunction [108,120]. At least five major gut-derived uremic toxins have been associated with CV disease and mortality in CKD: indoxyl sulfate, indole-3 acetic acid, *p*-cresol sulfate, TMAO, and phenylacetylglutamine [120]. In a small study that included nine CKD patients per group, and which had a short duration of 6 months, LPD with or without inulin prebiotic supplementation was reported to modify the gut microbiome, increase serum bicarbonate, and improve physical function scores [121], but the investigators did not examine CKD progression or levels of gut-derived uremic toxins. Future studies should examine the role of PLADO regimens on gut microbiome in CKD patients.

### **Similarities and distinctions between PLADO and other CKD diets**

In contrast to other diets used for the management of CKD, the PLADO offers a more pragmatic and patient-centered nutritional management which is aligned with contemporary dietary management

goals. Unlike the diets used in the MDRD study and other studies that focused on hard outcomes, the premise of PLADO is based on its expected effects on both hard endpoints and patient-centered outcomes, including health-related quality of life, uremic symptoms, and diet palatability, while safety and adequacy remain among important goals. It is important to note that the MDRD study was conducted in the early 1990s under dietary practices that are not relevant to contemporary practice. While high-protein diets such as keto, Atkins, and Paleo are popular in contemporary culture, there has been growing interest in plant-based diets across the lay and scientific communities and professional societies, including the National Kidney Foundation [122], which were not considered in the MDRD study.

Restricted protein diets that are partially to entirely plant-based are more broadly generalizable to the adult populations as compared to the prior LPD trials, including the MDRD study. PLADO can be safely recommended to both patients with early CKD, including those with any degree of proteinuria regardless of etiology [123], as well as to late-stage CKD populations, including those with an eGFR <45 mL/min/1.73 m<sup>2</sup>, without a lower eGFR limit, to take the advantage of the effects of LPDs in controlling uremia and averting the need for dialysis. This stands in sharp contrast to the MDRD study, participants of which had relatively high eGFRs (eGFR 25–55 mL/min/1.73 m<sup>2</sup>), and which focused on slowing the progression of moderate CKD. Indeed, in the MDRD study, patients did not have diabetes [124], whereas PLADO can be non-differentially prescribed to both patients with and without diabetes with any degree of severity of CKD, consistent with the broader unmet need in the adult CKD population. It is important to note that polycystic kidney disease patients, who usually have slower CKD progression rates, comprised 24% of the MDRD study participants [124].

### **Role of dietitians in PLADO**

The successful implementation of plant-based restricted protein diets is dependent on the engagement of dietitians who are well trained in the field of nondialysis CKD [125]. Dietitians should assess regularly the dietary protein and energy as well as micronutrient intakes of CKD patients by both periodic dietary assessments and 24-hour urine collections to estimate dietary intakes of macro- and micronutrients and to evaluate and improve adherence to dietary recommendations [1]. Behavior change counseling by dietitians is a key skill set that is critical in successful lifestyle and habit modifications. Easy-to-use telehealth

alternatives are important to overcome existing and emerging challenges in dietetic education, including under the COVID-19 pandemic and other restrictions, so that patients are provided with pragmatic tools and comprehensible and consistent dietary information and skills, which fosters ownership and self-monitoring in kidney health management such as healthy kitchen approaches [126,127].

Unfortunately, however, an overwhelming majority of CKD patients never meet with a CKD-specialized dietitian prior to dialysis initiation, and most patients remain uninformed about the role of diet in disease progression and management. Among clinicians and patients, lack of awareness about the benefits of plant-dominant, low-protein dietary interventions (other than low-potassium diets) and available insurance reimbursement for medical nutrition therapy under the guidance of a registered dietitian are significant barriers. In many regions, especially in North America and Europe, the focus and expertise of the dietitians have traditionally been centered on dialysis patient care as opposed to preventative nondialysis-dependent CKD. Past and recent reports suggest underutilization of dietetic manpower and expertise for the purpose of nondialysis CKD care [74]. A collective groundswell of events has recently occurred which aims to improve CKD care: the World Kidney Day focuses on the reduction of the onset and progression of CKD through primary, secondary, and tertiary measures [128]; the US Presidential Executive Order, “Advancing American Kidney Health” [129], refocuses on kidney care from dialysis incentives to avoidance of kidney failure; the US Veterans Health Administration issued Directive 1053, “Chronic Kidney Disease: Prevention, Early Recognition, and Management,” establishing federal policy targeting CKD prevention through integrated care, including medical nutrition therapy [130], and, the advocacy of renal dietitians for patient-centric LPD regimens containing fewer animal products and more plant-based sources of protein such as PLADO [131]. This is a sharp contrast to prior LPD recommendations with less flexible regimens such as strict plant-based dieting or very low DPI of  $<0.4$  g/kg/d combined with supplements, which may be less palatable, unsustainable, and nonpragmatic for broad application in the real-world scenarios of CKD patient care.

### Recommendations for practical implementation of PLADO

After the first 3 months, which includes preliminary education on LPD regimens with  $>50\%$  plant sources and acquiring food preparation skills, participating CKD

patients should be assessed every 3–6 months by the dietitian. During each visit, dietary reeducation along with dietary assessment should be conducted and patient’s progress in reaching the goals should be examined. In line with the pragmatic nature of PLADO regimens, the dietary reeducation and follow-up visits can be performed in parallel with routine follow-up CKD clinic visits on the same days of the ambulatory clinic appointments, thus avoiding the burden of additional diet-related travels to the CKD clinic. In addition to in-person visits, there could be monthly to trimonthly telephone calls with the CKD patients under CKD therapy, or even more frequently if needed, to reinforce diet planning and adherence and to answer questions about the preparation of plant-dominant meals and cooking questions. Adherence to PLADO should be evaluated by comparing the LPD goals, that is,  $0.6\text{--}0.8$  g/kg/d and  $>50\%$  plant sources, to the estimated DPI (eDPI) using 24-hour urine nitrogen (see later) and 3-day diet assessments, respectively. Complementary dietary education of the patients and their care partners should be provided both during the face-to-face visits and via phone calls.

The specialized knowledge and services of a renal dietitian ensure accurate nutrition education, meal planning, and evaluation of body composition to sustain health. Components of a CKD nutrition evaluation may include the following (see Table 29.5): (1) dietary education for LPD with  $>50\%$  plant-based protein sources; (2) dietary assessment using a 3-day diet diary with interview; (3) simplified anthropometry that includes triceps and biceps skinfolds [132] and mid-arm circumference [133]; (4) body fat estimation using either bioimpedance analyses or near-infrared interactance [134–136]; (5) the malnutrition-inflammation score, also known as Kalantar score [137–140], including subjective global assessment [141]; and (6) hand-grip strength test [142]. The dietary education along with the previous evaluations usually takes 30 minutes to 1 hour of the dietitian’s time during each visit according to our previous and ongoing nutritional clinic operations.

### Concurrent pharmacotherapy and other interventions

Regardless of the type of the dietary regimen, participation in the PLADO plan does not interfere with any other aspects of the CKD patient care, including prescribed medications such as angiotensin pathway modulators, other antihypertensive medications, antidiabetic medications such as SGLT2 inhibitors, phosphorus binders, potassium binders, and sodium bicarbonate. Indeed, it is expected that dietary protein restriction will have a synergistic effect on these

**TABLE 29.5** Overview of the recommended ambulatory visits and tests under the plant-dominant low-protein diet (PLADO) regimen.

Timeline of for PLADO therapy visits		“Run-in” period			Year 1 (quarterly)			Years 2 + (semiannual)				Needed time
PLADO months		0	1	3	6	9	12	18	24	30	36	
Lab tests	History and physical examination with updates on clinical and dietary status	X	x	x	x	x	X	x	x	x	x	10–20 min
	Routine lab panel: CMP/LFT, anemia, MBD, A1c	X		x	x	x	X	x	x	x	x	<10 min
	Spot urine, urinalysis, protein, albumin, and creatinine	X		x	x	x	X	x	x	x	x	<5 min
	24 h urine: Nitrogen, Na, K, creatinine, alb, and prot.	X		x	x	x	X	x	x	x	x	Collected at home
Dietitian visit	eGFR assessment and creatinine and urea clearance	X		x	x	x	X	x	x	x	x	
	Dietary education for LPD >50% plant-based	X	x	x	x	x	X	x	x	x	X	10–20 min
	Dietary assessment, 3-day diet diary with interview	X	x	x	x	x	X	x	x	x	X	10–20 min
	Anthropometry: triceps and biceps skinfolds, mid-arm circumference <sup>a</sup>	X		x	x	x	X	x	x	x	X	2–4 min
	Body fat estimation <sup>a</sup>	X		x	x	x	X	x	x	x	X	1–2 min
	Malnutrition-inflammation score <sup>a</sup>	X		x	x	x	X	x	x	x	x	2–5 min
	Handgrip strength test <sup>a</sup>	X		x	x	x	X	x	x	x	x	1–2 min
	Phone calls to reinforce PLADO education, adherence, and meal preparation	x	x	x	x	x	X	x	x	x	x	10–30 min
Questionnaires	Diet palatability and appetite questionnaire	x	x	x	X	x	X	x	x	x	x	15–30 min
	Food frequency questionnaire <sup>a</sup>	x			x		X	x	x	x	x	15–30 min
	Quality of life: KDQOL including SF36 quest <sup>a</sup>	x		x	x	x	X	x	x	x	x	10–15 min
	Uremic symptoms questionnaire	x		x	x	x	X	x	x	x	x	10–15 min

<sup>a</sup>These items are more relevant to sophisticated centers or under research protocols.

Abbreviations: alb, Albumin; CMP, comprehensive metabolic panel; eGFR, estimated glomerular filtration rate; K, potassium; Na, K, creatinine; KDQOL, Kidney disease quality of life; LFT, liver function tests; LPD, low-protein diet; MBD, Mineral and bone disorder; Na, sodium; prot., protein; RD, Registered dietitian; SF36, short form with 36 items of quality of life.

pharmacotherapies [76]. The inclusion of plant-based foods may necessitate a reduction in any of these medications over time as the relevant parameters improve.

### Laboratory tests for nutritional management of CKD

Consistent with the pragmatic and cost-efficient nature of the PLADO regimen, all relevant laboratory tests are performed in the clinical laboratories of the respective medical centers typically as part of routine CKD care. With the exception of a semiannual serum vitamin B12 level, quarterly to semiannual laboratory tests include routine chemistry panels (including serum Na, K, CO<sub>2</sub>, Cl, urea, creatinine, and glucose), liver function tests, hemoglobin A1c, anemia, and mineral and bone disorder (MBD) parameters, including calcium, phosphorus, and

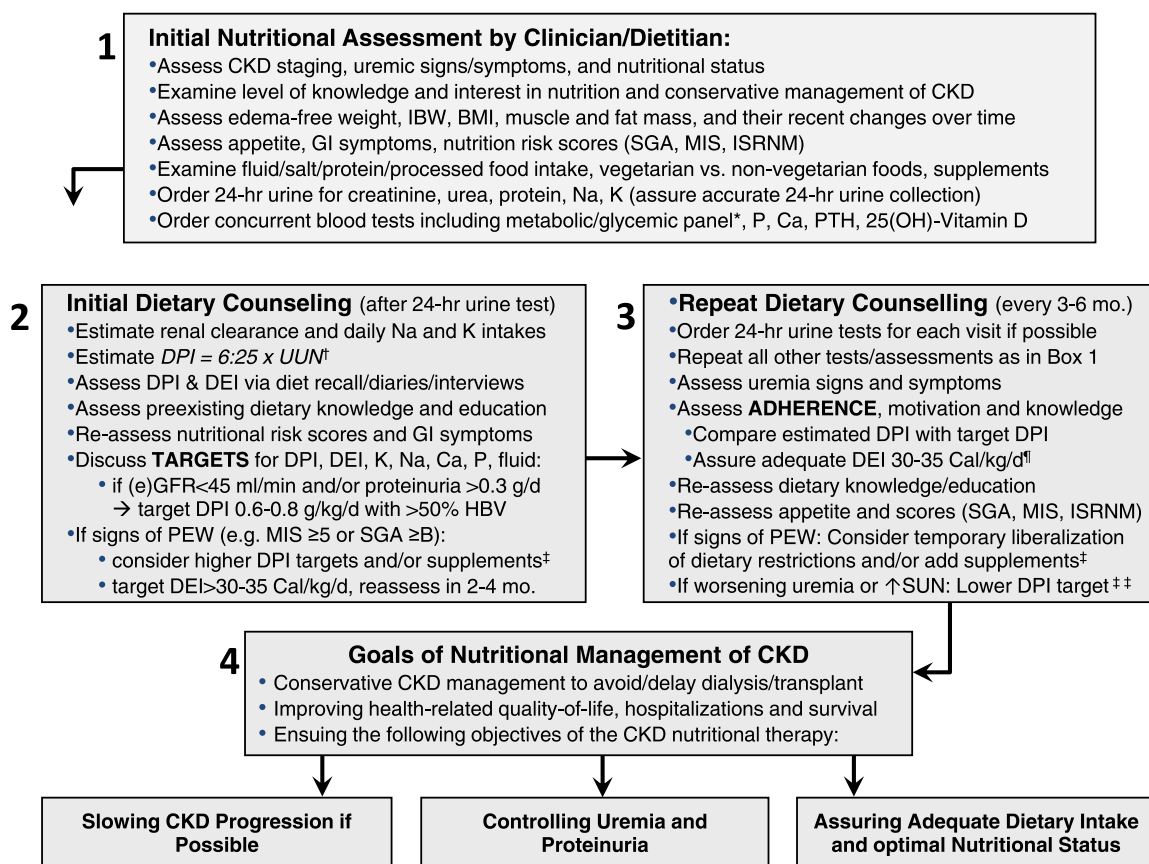

parathyroid hormone. Urinalysis and spot urine for urinary protein/albumin and creatinine should be tested, and eGFR is calculated [143]. Participating patients are instructed to collect 24-hour urine samples according to the directions that should be repeated during each ambulatory visit and/or each phone call, that is: not collecting the first urine in the morning of Day 1, collecting the first urine in the morning of Day 2 as the last collection component, and the entire micturition in-between. The 24-hour urine should include measurements of urine urea nitrogen (UUN), sodium (UNa), potassium UK, creatinine (UCr), albumin, and protein, as well as urine volume (UV). The following measures should be calculated and reviewed by both the nephrologist and dietitian during each visit [1] (Fig. 29.5):

1. Creatinine clearance:  $UCr \cdot UV / SCr$  in mL/min, and to compare to eGFR.

2. Creatinine index:  $\text{UCr/weight (mg/kg)}$ , to identify 24-hour urine collection inaccuracies, including under- and overcollections by comparing it to the expected value of 1–2 mg/kg/d for women and 1.5–2.5 mg/kg/d for men.
  3. eDPI:  $\text{UUN} \times 6.25 + 0.03 \times \text{weight (g/kg/d)}$ ; for patients with substantial proteinuria >3 g/d, the daily proteinuria amount is added to the eDPI [1,74].
  4. Estimated dietary Na intake:  $\text{UNa in mmol/44 (g/d)}$ .
  5. Estimated dietary K intake:  $\text{UK in mmol/25 (g/d)}$ .
  6. 24-hour urinary protein and albumin excretion (mg/d).
- See Table 29.5 for the overview of the laboratory tests.

### Suggested self-administered questionnaires

Based on the goals and the extent of the operation and resources of the CKD clinic, some to all of the following self-administered questionnaires can be used during each or alternating ambulatory visit: (1) diet, palatability, and appetite questionnaire: the appetite component allows grading appetite and recent changes [144]. The palatability component includes 12 items and grades palatability and feasibility of dietary intervention [144]. These items are combined with the diet assessment of the HEMO study [145]. (2) Quality of life KDQOL, including SF36: This has been used and validated

**FIGURE 29.5** Proposed algorithm and steps for the approach to the nutritional management of patients with chronic kidney disease. \*Comprehensive metabolic and glycemic panels include electrolytes, SUN, creatinine, glucose, A1c, liver function tests, and the lipid panel. <sup>†</sup>The full equation is:  $\text{DPI} = 6.25 \times \text{UUN} + 0.03 \times \text{IBW}$ . Add the amount of daily proteinuria in grams if proteinuria >5 g/d. Calculate the *creatinine index* (24-h urine creatinine divided by actual weight or IBW if obese) and compare it to the expected value of 1–1.5 g/kg/d for women and 1.5–2 g/kg/d for men. <sup>‡</sup>Dietary supplements can be added to provide additional sources of energy and/or protein, including—but not limited to—CKD-specific supplements, essential amino acids, or keto-analogs (ketoacids) of amino acids. <sup>¶</sup>To ensure adequate DEI of at least 30–25 Cal/kg/d, higher fat intake can be considered, for example, unsaturated fats, omega 3—rich flaxseed, canola, and olive oil. <sup>‡‡</sup>If worsening uremic signs and symptoms occur, DPI <0.6 g/kg/d with or without supplements can be considered. BMI, Body mass index; CKD, chronic kidney disease; d, day; DEI, dietary energy intake; DPI, dietary protein intake; eGFR, estimated glomerular filtration rate; GI, gastrointestinal; HBV, high biologic value; IBW, ideal body weight; ISRNM, International Society of Renal Nutrition and Metabolism; K, potassium; MIS, malnutrition-inflammation score; Na, sodium; PEW, protein-energy wasting; Phos., phosphorus; PTH, parathyroid hormone; SGA, subjective global assessment; SUN, serum urea nitrogen; UUN, urine urea nitrogen. Source: Adapted from Kalantar-Zadeh K, Joshi S, Schlueter R, Cooke J, Brown-Tortorici A, Donnelly M, et al. Plant-dominant low-protein diet for conservative management of chronic kidney disease. *Nutrients* 2020;12(7). <https://doi.org/10.3390/nu12071931>. extensively [139]. (3) Uremic symptoms questionnaire: This questionnaire is derived from the “Symptom Assessment Instrument” by Weisbord et al. [146], which was created and validated in US veterans with stage 5 CKD. (4) Self-perception and relationship questionnaire: This item will assess the psychosocial–spiritual well-being using the 28-item scale [147]. (5) Food frequency questionnaire (FFQ) [148]: This questionnaire has been developed by Kalantar-Zadeh et al. using the Block FFQ from UC Berkeley and can be used semiannually to annually (see Table 29.5).

### Diet safety and transient dietary regimen suspension

Once a patient has completed the 3-month run-in period, including dietary education and food preparation training and adjustments, there should be periodic (every 3–6 months) ambulatory visits with continued data collection and review. If PEW signs are observed, or in the case of an event that requires suspension of the LPD such as hospitalization with AKI, regardless of dialysis need, or major adverse cardiovascular events, the LPD can be transiently suspended, and the patient can resume the LPD and the study protocol at a later time, usually within 90 days of the suspension of the dietary regimen participation if deemed safe. Serum potassium levels  $>5.5$  mEq/L will preferentially be managed by potassium binders (first line) and/or reducing the potassium-rich components of the diet (second line), as opposed to the current standard of care in that traditional low-potassium dietary adjustments are pursued as the main approach, followed as needed by the administration of potassium binders.

### Challenges and pitfalls of the dietary management of CKD

As stated earlier, the proposed plant-dominant diet may cause hyperkalemia and could, thus, be hazardous to patients with advanced CKD. Nephrologists and dietitians should closely monitor patients during the 3-month run-in period and thereafter for adverse events. Dietitian support is necessary for appropriate education on culinary strategies to reduce excessive potassium content while preserving flavor and nutrition. Physicians should take appropriate actions, including the use of potassium binders or suspension of the patient's participation, if this should be the safest approach. We do not expect that most patients on plant-based diets will develop hyperkalemia, as these diets are alkalinizing and alter intestinal transit time

(see earlier), especially if dried fruit, juices, smoothies, and sauces can be minimized or avoided along with judicious avoidance of processed food with added potassium-based additives and preservatives [100]. Those who are extremely prone to develop hyperkalemia would display this early in the course of the intervention and the PLADO would be discontinued if hyperkalemia cannot be controlled. Less constipation as a result of PLADO is associated with favorable CV and renal outcomes [149,150].

It is important to note that the emerging standard of care in CKD is a restricted protein diet of 0.55–0.6 g/kg/d for nondiabetic CD and 0.6–0.8 g/kg/d for diabetic CKD according to the updated kidney disease outcomes quality initiative (KDOQI) nutrition guidelines as of September 2020 [151], and if this is implemented, this is in support of our PLADO regimen. Whereas it is true that an LPD should be the stated goal according to the 2020 KDOQI guidelines, this is typically not followed in everyday clinical practice, where dietary interventions are driven by biochemical abnormalities such as hyperkalemia or hyperphosphatemia. Indeed, prior KDOQI guidelines had recommended DPI of 0.8 g/kg/d without any clear range, which is rarely pursued in a real-world scenario.

It could be argued that under the PLADO regimen, there is no clear meal plan. However, this indeed ensures the intended flexibility and pragmatism of the PLADO regimen. The patient and the dietitian should work together in establishing a patient specific “Healthy Kitchen for CKD” and patients and their care partner should gain experience in implementing patient-centered dietary interventions for CKD management. Careful and balanced industry partnership can be sought to develop innovative “Healthy Kidney Diet Plans” to help people with CKD change their diet to delay the progression of the disease and to defer and prevent kidney failure.

It has been argued that many people with CKD enjoy eating high amounts of meat, and it is highly unlikely that they will adopt an LPD with  $>50\%$  plant sources, especially since many dietitians recommend a high-protein diet as an approach against obesity and diabetes. Several authors of this review chapter, including both nephrologists and dietitians, have successfully implemented an LPD and plant-dominant diet education in CKD in their respective medical centers. They are aware of the cultural and dietary challenges, including in Americans and other Westerners as described in their published reports [74], and have been able to introduce and implement the PLADO regimens as described here.

Another potential challenge is the misconception related to the definition of the conservative

management of advanced CKD, which is often confused with palliative and supportive care toward the end of life and without requiring special diets. This incorrect assumption is the result of confusing different types of conservative management of CKD, and their similarities and distinctions that have recently been better clarified [152], in that a dietary approach, including PLADO, is a “preservative” management of CKD and a life-sustaining and kidney rejuvenating alternative.

To summarize the last several sections of this chapter, plant-based foods and plant-dominant recipes and meal plans have been identified as a fundamental dietary component for health among a wide variety of eating patterns. Plant-based diets are an umbrella term used to describe eating patterns that included a large proportion of plant-dominant foods. Examples of this include flexitarian, vegetarian, Mediterranean, PLADO diet, and vegan diets (Table 29.6) [62]. Unrefined, whole-, plant-based foods are recommended over their highly processed forms. The consumption of whole-, plant-based foods has been shown to be useful in the prevention and treatment of many of the lifestyle-related scourges of Western societies, including T2DM, obesity, hypertension, and hyperlipidemia. In recent years, their utility for CKD and its resultant benefits and potential challenges have become increasingly apparent [62].

## Dietary sodium and fluid intake

The association between dietary sodium and blood pressure is most pronounced in persons who consume high sodium ( $>4$  g/d), have underlying hypertension, or over age 55 years [153]. In established CKD, dietary sodium restriction is invariably recommended to control fluid retention and hypertension, and to improve CV risk profiles [154]. However, it is not clear that dietary salt restriction can slow the progression of established kidney disease. Since CV trials involving dietary sodium restriction often exclude patients with renal disease, there are limited relevant interventional data in this population [155]. Lower sodium intake enhances the effects of an LPD and angiotensin modulation therapy in decreasing intraglomerular pressure (Fig. 29.1) [156] and may decrease proteinuria and slow kidney disease progression [157]. Observational studies using urinary sodium excretion as a surrogate of salt intake have yielded inconsistent data ranging from null [158] to positive associations [159] between dietary sodium intake and renal disease progression. A recent longitudinal study using serial 24-hour urine collections in 3939 patients with CKD suggested that the highest versus lowest quartile of urinary sodium excretion ( $\geq 4.5$  vs  $<2.7$  g/d) was associated with 45% higher mortality and 54% higher risk of disease progression [159]. Incrementally worse CV outcomes were

TABLE 29.6 Examples and descriptions of various plant-based diets.

Diet type	Description
DASH diet	A specific dietary strategy designed to emulate the health-promoting effects of plant-based diet but allow for some animal-based foods, like lean meat and low-fat dairy. Modern iterations have emphasized the unprocessed forms of fruits, vegetables, legumes, and grains (as opposed to fruit juices, refined grains, etc.)
Mediterranean	Although definitions and practices vary, particularly in time and place, the Mediterranean diet typically emphasizes whole, plant foods from that area with moderate consumption of lean meats, dairy, and seafood. Added sugars, processed foods, and red meat are generally excluded but healthy fats like olive oil are included. The recently updated KDOQI nutrition guidelines give a grade 2C recommendation for the potential of Mediterranean diets to improve lipid profiles in patients with nondialysis CKD
Flexitarian	Also commonly referred to as a “semivegetarian.” Represents a diet that emphasizes plant-based foods but may periodically include meat and other animal-based foods
Vegetarian	A diet that excludes meat (beef, pork, and chicken) but may include fish, dairy, or eggs and often specified as a pescatarian, lacto vegetarian, or ovo vegetarian, respectively. Combinations of these are possible
Whole-food, plant-based	A diet that emphasizes the consumption of whole-, plant-based foods as opposed to refined or processed plant foods (like potato chips or white bread) while still typically avoiding animal-based foods. It is also the diet most widely promulgated by health professionals recommending a plant-based diet
Vegan	A diet and, in some cases, a lifestyle that avoids the use of products derived from animals
PLADO	Plant-dominant, low-protein diet for patients with kidney disease: 0.6–0.8 g/kg/d dietary protein with $>50\%$ from plant-based sources, dietary sodium of $<4$ g/d sodium ( $<3$ g/d if uncontrolled hypertension or edema), and dietary energy of 30–35 Cal/kg ideal body weight per day

CKD, Chronic kidney disease; DASH, Dietary Approaches to Stop Hypertension.

Adapted from Joshi S, McMacken M, Kalantar-Zadeh K. Plant-based diets for kidney disease: a guide for clinicians. *Am J Kidney Dis* 2021;77:287–96. <https://doi.org/10.1053/j.ajkd.2020.10.003>. PubMed PMID: 33075387. <https://www.ncbi.nlm.nih.gov/pubmed/33075387>.

observed when dietary sodium intake exceeded 4 g/d [160]. Recent observations in the general population suggest a J-shaped association in which both higher and lower dietary sodium intake (>5 and <3 g/d) were associated with higher risk of CV disease and death [161]. Considering these recent data and lack of evidence in kidney disease populations to support extrapolating the *RDA* of <2.3 g/d (<100 mmol/d) that is often recommended for CV disease management, we recommend a dietary sodium intake of <4 g/d (<174 mmol/d) for the overall management of CKD and its associated risks, and <3 g/d (<131 mmol/d) for specific management of symptomatic fluid retention or proteinuria. Evidence that safely supports a more stringent sodium restriction of <1.5 g/d (<87 mmol/d) given the risk of hyponatremia and adverse outcomes in renal insufficiency is lacking [162], but individualized decisions should override a generalized application of sodium restriction (Table 29.7).

Whereas adequate fluid intake may mitigate risk of kidney disease [164], patients with renal insufficiency generally have isosthenuria; thus in patients with stage 3 CKD, fluid intake should be restricted to <1.5 L per day to avoid hyponatremia [162], but adjustments of that limit for hot climate and other conditions with high insensible fluid losses are imperative. Adjunctive therapy with loop diuretics is often prescribed, particularly in patients who tend to develop symptomatic fluid retention or hyponatremia, given the association of such conditions in CKD with poor outcomes [162].

### Dietary potassium

Many potassium-rich foods, such as fresh fruits and vegetables, are considered healthy choices for most people, given their higher fiber and vitamin content and lower acidogenicity [165]. In some large population cohorts at high-risk for CV disease [158] or diabetes [166], higher urinary potassium excretion is associated with lower likelihood of all renal complications except for hyperkalemia. Given the well-established association of higher dietary potassium with lower sodium intake and lower incidence of hypertension, stroke, nephrolithiasis and kidney disease, a relatively high daily potassium intake of 4.7 g/d (120 mmol/d) is recommended for healthy adults, including those at high risk of kidney disease [167]. There are, however, inconsistencies in the epidemiologic data pertaining to potassium intake in preexisting renal disease, because higher dietary potassium intake may be associated with higher risk of disease progression [159]. In very advanced CKD the highest versus lowest quartile of dietary potassium intake is associated with a

2.4-fold higher death risk independent of serum potassium level and other nutritional parameters [168]. In epidemiologic studies, both moderately low (<4.0 mmol/L) and high (>5.5 mmol/L) serum potassium levels are associated with faster kidney disease progression [169]. In hyperkalemic patients, especially in those with more advanced stages of kidney disease, dietary potassium restriction is often recommended to avoid hyperkalemia. However, excessive dietary restrictions expose patients to less heart-healthy and more atherogenic diets [170], and worsen constipation, which may result in higher gut potassium absorption [94]. Despite a higher predilection for hyperkalemia with progression of kidney disease, few studies have examined the effects of dietary potassium restriction, or methods of extracting potassium during food preparation and cooking. It is not clear whether potassium-binding agents can allow the liberalization of dietary potassium intake with the inclusion of healthier potassium-rich food items [165]. In patients with a tendency toward hyperkalemia (>5.5 mEq/L), a dietary potassium restriction of <3 g/d (<77 mmol/d) is recommended, with the stipulation that a balanced intake of fresh fruits and vegetables with high fiber should not be compromised (Table 29.7).

### Dietary phosphorus

In the general population, higher plasma phosphorus levels have been associated with an increased risk of incident kidney disease [171]. Overt hyperphosphatemia is infrequent in stages 1–3 of CKD, given the heightened expression and release of parathyroid hormone and FGF-23 in renal insufficiency, which promote urinary phosphorus excretion [172]. However, elevated PTH and FGF-23 can cause renal bone disease, left ventricular hypertrophy, vascular calcification, and accelerated kidney disease progression from vascular and tubulointerstitial injury (Fig. 29.2), highlighting the importance of dietary phosphorus management even without apparent hyperphosphatemia [173]. While an LPD also decreases phosphorus intake, different proteins contain varying quantities and bioavailability of phosphorus; for instance the phosphorus-to-protein ratio of egg whites and egg yolks are 1–2 and 20–30 mg/g, respectively [174]. The gut absorption of plant phosphorus and fibers, mostly in the form of phytates, is less than meat (30%–50% vs 50%–70%, respectively) [82]. As food additives include readily absorbable inorganic phosphorus (up to 100%), ingesting processed foods causes an even higher phosphorus burden [175]. A dietary phosphorus restriction to <800 mg/d is recommended among patients with moderate-to-advanced kidney disease, and processed

TABLE 29.7 Recommended dietary and nutrient intake for different stages of kidney disease in adults.

	Normal kidney function (eGFR >60 <sup>a</sup> ) and no proteinuria, but at higher CKD risk, for example, diabetes, hypertension, or solitary kidney <sup>b</sup>	Mild-to-moderate CKD (eGFR 30– <60 <sup>a</sup> ) without substantial proteinuria (<0.3 g/d) <sup>c</sup>	Advanced CKD (eGFR <30 <sup>a</sup> ) or any CKD with substantial proteinuria (>0.3 g/d) <sup>c</sup>	Transitioning to dialysis therapy with good RKF, including incremental dialysis preparation <sup>c</sup>	Prevalent dialysis therapy, or any CKD stage with existing or imminent PEW <sup>d</sup>
Dietary protein (g/kg/d based on IBW) <sup>e</sup>	<1.0 g/kg/d, increase proportion of plant-based proteins	<1.0 g/kg/d (consider 0.6–0.8 if eGFR <45 mL/min 1.73 m <sup>2</sup> and fast progression)	0.6–0.8 g/kg/d, including 50% HBV, or <0.6 g/kg/d with addition of EAA/KA	0.6–0.8 g/kg/d on nondialysis days (e.g., incremental dialysis) and >1.0 g/kg/d on dialysis days	1.0–1.2 g/kg/d, may require >1.5 g/kg/d if hypercatabolic
Dietary sodium (g/d)	<4 g/d (<3 g/d for HTN) <sup>f</sup>	<4 g/d, avoid <1.5 g/d if hyponatremia likely	<3 g/d, avoid <1.5 g/d given high likelihood of hyponatremia	<3 g/d	<3–4 g/d
Dietary potassium (g/d)	Same as recommended for the general population (4.7 g/d)	Same as the general population unless frequent or severe hyperkalemia excursions likely	<3 g/d if hyperkalemia occurs frequently while maintaining high fiber intake	<3 g/d if hyperkalemia occurs frequently while maintaining high fiber intake	<3 g/d <sup>g</sup> , target high fiber intake (see under fibers)
Dietary phosphorus (mg/d) <sup>h</sup>	<1000, minimize added inorganic P in preservatives and processed foods	<800, minimize added inorganic P, encourage more vegetarian food (see next)	<800, minimize added inorganic P, more vegetarian food (see next)	<800, minimize added inorganic P. Consider P binder therapy	<800, minimize added inorganic P. Add P binders as needed
Dietary calcium (mg/d)	1000–1300 mg/d (to be adjusted for age)	800–1000 mg/d	800–1000 mg/d	800–1000 mg/d or less	<800 mg/d
Fibers, alkali, and vegetarian foods	25–30 g/d, target higher proportion (>50%) of plant-based foods such as DASH diet	25–30 g/d or more, higher proportion (>50%) of plant based foods	25–30 g/d or higher, consider >70% vegetarian foods	25–30 g/d or higher	25–30 g/d or higher, suggest avoiding strict vegan dieting
Energy <sup>i</sup> (Cal/kg/d)	30–35 Cal/kg/d <sup>j</sup> adjust to target weight reduction if BMI >25 kg/m <sup>2</sup>	30–35 Cal/kg/d, increase proportion with LPD	30–35 Cal/kg/d, increase proportion with LPD	30–35 Cal/kg/d	30–35 Cal/kg/d, target higher if PEW exists or imminent
Fats	Mostly mono- and poly-unsaturated lipids, including omega 3 fatty acids	Mostly mono- and poly-unsaturated lipids, including omega 3 fatty acids, increase proportion with LPD	Mostly mono- and poly-unsaturated lipid, including omega 3 fatty acids, increase proportion with LPD	Mostly mono- and poly-unsaturated lipid, including omega 3 fatty acids	Mostly mono- and poly-unsaturated lipid, including omega 3 fatty acids
Vitamin D	Nutritional D (ergo- or cholecalciferol) as needed	Nutritional D or calcifediol, consider adding 1α-OH D analogs in progressive sHPT	Nutritional D or calcifediol, add 1α-OH D analogs in progressive or symptomatic sHPT	1α-OH D analogs to control sHPT	1α-OH D analogs to control sHPT, add calcimimetics as needed
Other vitamins and trace elements	Recommend daily multivitamin intake	Avoid aluminum-based medications, monitor iron indices, and ensure iron therapy as needed	Avoid aluminum and magnesium-based agents. Treat iron deficiency	Avoid aluminum, and magnesium-based agents. Treat iron deficiency	Avoid aluminum and magnesium-based agents. Treat iron deficiency
Management of weight	Lipid and weight reduction strategies target BMI in	Avoid excessive weight loss, consider	Identify unintentional weight	Identify unintentional	Avoid weight loss or BMI <23 kg/m <sup>2</sup> unless

TABLE 29.7 (Continued)

	Normal kidney function (eGFR >60 <sup>a</sup> ) and no proteinuria, but at higher CKD risk, for example, diabetes, hypertension, or solitary kidney <sup>b</sup>	Mild-to-moderate CKD (eGFR 30–<60 <sup>a</sup> ) without substantial proteinuria (<0.3 g/d) <sup>c</sup>	Advanced CKD (eGFR <30 <sup>a</sup> ) or any CKD with substantial proteinuria (>0.3 g/d) <sup>c</sup>	Transitioning to dialysis therapy with good RKF, including incremental dialysis preparation <sup>c</sup>	Prevalent dialysis therapy, or any CKD stage with existing or imminent PEW <sup>d</sup>
and cardio-vascular risks	18.5–25 kg/m <sup>2</sup> range, recommend regular exercise training	careful exercise training, follow conventional lipid targets	loss and intervene with higher energy and protein	weight loss and intervene with higher energy and protein	required for imminent kidney transplantation or other life-saving interventions
Fluid management	No fluid restriction, adequate hydration >1.5 L/d (if risk of hyponatremia is minimal)	<1.5 L/d if edematous state or hyponatremia, consider adding diuretics	<1.5 L/d <sup>k</sup> , consider loop diuretics and titrate the dose or sliding scale dosing <sup>l</sup>	<1.5 L/d <sup>k</sup> , consider more frequent high-dose loop diuretics	<1 L/d, avoid excessive ultrafiltration on dialysis

<sup>a</sup>The unit for eGFR is mL/min/1.73 m<sup>2</sup> BSA.

<sup>b</sup>Solitary kidney can be congenital, acquired, or surgical, including status postdonor or cancer nephrectomy.

<sup>c</sup>Prevalent renal transplant recipients are often in the two categories of eGFR 30–<60 and >30 mL/min/1.73 m<sup>2</sup>, or transitioning to dialysis and can be approached similarly.

<sup>d</sup>PEW according to the International Society of Renal Nutrition and Metabolism criteria [163].

<sup>e</sup>The IBW is to be used for kg in the denominator of all dietary recommendations especially in persons with a BMI >30 kg/m<sup>2</sup>. IBW can be estimated in kg in males (=50 + 2.3 kg for each inch over 5 ft) and females (=45.5 + 2.3 kg for each inch over 5 ft).

<sup>f</sup>In patients with heart failure the recommendations of the American Heart Association (<http://www.heart.org>) can be considered. The American Heart Association recommends no more than 2.3 g/d (equivalent of a teaspoon salt) and suggests an ideal limit of no more than 1.5 g/d (source: <https://sodiumbreakup.heart.org>).

<sup>g</sup>In hypokalemic peritoneal dialysis patients, higher potassium intake should be targeted.

<sup>h</sup>Dietary phosphorus restriction is independent of hyperphosphatemia.

<sup>i</sup>Carbohydrates provide 40%–60% of the daily energy intake, should be natural (unrefined) and complex with high fiber content (see under fibers).

<sup>j</sup>In obese patients, lower energy ranges can be targeted.

<sup>k</sup>In the case of worsening edema, more stringent fluid restrictions may be necessary such as <1 L/d.

<sup>l</sup>Sliding scale dosing of loop diuretics instructs upward dosing for fluid retention and downward dosing for volume depletion based on daily weight and other parameters.

1α-OH D, 1-alpha-hydroxylated vitamin D; BMI, body mass index; BSA, body surface area; Cal, kilo-calorie; CKD, chronic kidney disease; d, per day (such as in g/kg/d); D, vitamin D; DASH, Dietary Approaches to Stop Hypertension; DPI, dietary protein intake; EAA, essential amino acids; eGFR, estimated glomerular filtration rate in mL/min/1.73 m<sup>2</sup> BSA; HBV, high biologic value protein; HTN, hypertension; IBW, ideal body weight; KA, ketoacids (keto-analogs of amino acids); LPD, low-protein diet; P, phosphorus; PD, peritoneal dialysis; PEW, protein-energy wasting; RKF, residual kidney function; sHPT, secondary hyperparathyroidism.

foods with a higher phosphorus-to-protein ratio should be minimized. However, in patients transitioning to dialysis or who are at higher risk of PEW, restricting protein intake to control hyperphosphatemia may be associated with worse outcomes [176]. Thus an individualized dietary approach that incorporates ample use of phosphorus binders is warranted [177].

### Dietary calcium and vitamin D

The renal insufficiency-associated decline in 1,25 (OH)<sub>2</sub> vitamin D diminishes GI absorption of calcium; however, passive diffusion of ionized calcium continues and may lead to a positive calcium balance, aggravated by diminished urinary calcium excretion from secondary hyperparathyroidism [178]. Higher calcium release from bone in hyperactive renal bone disease enhances positive calcium balance and worsens vascular calcification [179]. Gut calcium absorption varies given differential dissociation and bioavailability of elemental calcium type; for instance

calcium citrate is more readily absorbable than calcium acetate [178]. Two recent balance studies suggested that an intake of 800–1000 mg/d of elemental calcium can achieve stable calcium balance in people with stages 3–4 CKD [178,180]. Hence, whereas the suggested calcium intake for persons without kidney disease is 1000–1300 mg/d [178], in moderate-to-advanced CKD 800–1000 mg/d of elemental calcium from all sources should suffice (Table 29.7) [178,180].

Nutritional vitamin D (cholecalciferol or ergocalciferol) may be offered to patients with kidney disease, whose circulating vitamin D levels are documented as low. In some studies, vitamin D analogs have been associated with decreased proteinuria in addition to the healing of renal osteodystrophy [181]. Notwithstanding inconsistent data about the requirement for and effect of vitamin D in certain CKD subpopulations, including inherently lower vitamin D and higher parathyroid hormone levels in African-Americans [182], 1-alpha-hydroxylated vitamin D agents or, calcifediol may be needed in addition to nutritional vitamin D to control progressive secondary hyperparathyroidism [183].

### **Vegetarian diet, fibers, and the microbiome**

Data from populations with largely vegetarian-based diets do not clearly distinguish a differential risk of plant- versus animal-based protein on the future likelihood of kidney disease [184]. Plant foods are recommended as part of many kidney disease prevention and management strategies, since these contain less saturated fatty acids, protein, and absorbable phosphorus and generate less acid and are rich in fibers, poly- and mono-unsaturated fatty acids, magnesium, potassium, and iron. In CKD a diet with a higher proportion (>50%–70%) of plant sources is associated with better patient outcomes [71]. Constipation can lead to higher retention of uremic toxins and hyperkalemia, whereas loose stools may enhance fluid loss and removal of nitrogenous products [150]. The protein in a vegetarian diet is less fermentable and has high fiber content, increasing peristalsis and bowel movements, and is associated with less production, exposure, and absorption of uremic toxins [185].

Uremia per se as well as dietary restrictions and pharmacotherapy, including antibiotics, may alter gut microbiome, and this may have a bearing on kidney disease symptoms and progression [186]. Microbiome modulation by dietary interventions such as probiotics may offer an opportunity to control production, degradation, and absorption of certain uremic toxins that are fermentation by-products of the gut microbial activities, including indoxyl sulfate, *p*-cresol, and trimethylamine [186]. Nutritional and pharmacologic approaches, including the use of ingestible absorbents and high fiber or vegetarian diets, are tested as a means to reduce gut absorption of uremic toxins to control uremic symptoms and to slow disease progression [187].

### **Carbohydrates, fats, and dietary energy**

When unrefined, carbohydrates comprise 40%–60% of the daily energy intake, and even higher with an LPD. Carbohydrates should be complexed with high fiber content to help reduce dietary phosphorus and protein, urea, and creatinine generation [86]. Such a diet also promotes a more favorable microbiome [188] with less constipation [150]. Unsaturated fat is the preferred lipid in the diet. Butter should be replaced by omega-3-rich flaxseed, canola, or olive oil [170]. A recent study suggested that dietary omega-3 fatty acid supplementation in diabetic patients with hypertriglyceridemia may reduce albuminuria and preserve renal function [189]. There is currently

no evidence demonstrating that low-fat diets, recommended by some guidelines, improve kidney disease outcomes. In an LPD, fat and carbohydrate should altogether comprise >90% of the daily energy intake requirement of 30–35 Cal/kg/d to avoid PEW [26]. Whereas in patients with diabetic kidney disease proper glycemic control should be maintained, adequate energy intake is needed to mitigate the risk of PEW and hypoglycemia that may occur more frequently with worsening kidney function.

### **Dietary management of acidosis in kidney disease**

Daily acid production results from bicarbonate losses in the gut (20–30 mEq/day), breakdown of amino and nucleic acids from proteins (20–30 mEq/day), and oxidation of carbohydrates and fats to lactic and ketoacids (10–20 mEq/day) [190]. The kidneys regenerate the bicarbonate used for buffering by the excretion of both net acid and acid buffers, including phosphate, and by ammoniagenesis through deamination of glutamine in the proximal tubule and its titration to ammonium in the collecting ducts with subsequent urinary excretion (Fig. 29.2) [190]. Hence, kidney disorders, including associated renal tubular defects, are often associated with chronic metabolic acidosis, which leads to glucocorticoid overproduction with resultant muscle wasting, worsens uremia-associated insulin resistance, and increases parathyroid hormone release [191]. Metabolic acidosis is associated with more rapid kidney disease progression and poorer survival. Hyperparathyroidism along with chronic buffering of acid by bone leads to a progressive loss of bone mineral and worsening renal osteodystrophy. Hence, reduced protein intake with a greater proportion of diet from vegetarian sources to correct acidosis improves bone mineralization and may slow protein breakdown and disease progression [192]. Adjunctive alkali therapy can also be considered to mitigate acidosis in CKD [193].

### **Trace elements and vitamins**

Patients with kidney disease often suffer from an imbalance of several critical trace elements and vitamins. Inadequate food intake may result in insufficient ingestion of antioxidant vitamins, including vitamins C and E and carotenoids, and with more advanced renal disease, vitamin deficiencies for folate, vitamin K, and calcitriol ensue [194]. Micronutrient imbalance in kidney disease may contribute to a higher burden

of oxidative stress, inflammation, and CV disease [194,195]. Among the trace elements, iron deficiency is most problematic, given the high frequency of GI blood losses in CKD [196]. Deficiencies of zinc, copper, and selenium may occur; in contrast, toxicities are more common with aluminum, magnesium, and possibly cadmium [194]. A recent study showed that 800 mcg/d of folic acid added to enalapril led to slower disease progression than enalapril alone [197]. Vitamin K supplementation may blunt the development of vascular calcification based on experimental models of CKD [198]. Daily intake of other vitamins and trace elements at conventional doses is often recommended both for persons at high risk for kidney disease and for those with established renal insufficiency (see additional references with comprehensive data on vitamins and trace elements in kidney disease) [194,195].

### Management of weight and CV risk

Evidence suggests that obesity, that is, body mass index  $>30 \text{ kg/m}^2$ , is associated with a higher lifetime risk of kidney disease [199]. In a recent study in over three million US veterans without prior kidney disease, obese men exhibited a more rapid decline in kidney function over time [200]. Conventional lipid and weight reduction strategies are recommended for persons at higher risk of kidney disease, including those who underwent a nephrectomy. Regular exercise training and general population targets for weight and CV risk reduction can be especially pursued in earlier stages of CKD [201]. Patients with hypertension are often recommended to follow an energy-controlled “Dietary Approaches to Stop Hypertension” diet, that is high in fruit, vegetables, whole grains, and low-fat dairy products and low in saturated fat, cholesterol, refined grains, sweets, and meat, and which may help with weight reduction in obesity [202]. The efficacy and safety of bariatric surgery to mitigate the risk of kidney disease are unclear [203]. A decrease in GFR has been observed after bariatric surgery, possibly because hyperfiltration is reduced; hence, the observation may have favorable implications [204]. Nevertheless, in more advanced CKD, greater longevity has been paradoxically reported with larger body size, which may reflect a more resilient nutritional profile. Hence, any unintentional edema-free weight loss warrants timely workup and dietary interventions, and unnecessary weight loss in advanced kidney disease should be avoided, unless absolutely required for an imminent kidney transplantation or other life-saving procedures [205].

### Conclusion and practice strategies

Given the high incidence and prevalence of CKD and urgent need for alternative disease management strategies, nutritional interventions with disease-specific dietary ranges (Table 29.7) are safe, patient-centered, and cost-effective interventions that may help provide greater longevity and longer dialysis-free interval to millions of people worldwide. Dietary protein, energy, and micronutrient intakes should be assessed regularly by both dietary assessments and 24-hour urine collections to evaluate and improve adherence, while excessive restrictions may be harmful and should be avoided. Additional studies are needed to fill existing knowledge gaps and to assure a more robust evidence-based approach in the nutritional management of CKD.

## Introduction

Patients with chronic kidney disease (CKD) manifest a wide range of metabolic derangements. These can either be attributed to the primary functions of the kidneys or the secondary abnormalities due to the uremic milieu. The kidneys excrete solutes and water and the deterioration of kidney function may lead to the accumulation of water and solutes, including nitrogenous-waste products, sodium, nonvolatile acids, phosphate, potassium, or other uremic toxins such as indoxyl-sulfate or *p*-cresol. The functions of kidney as an endocrine organ can deteriorate during the progression of CKD. This may be secondary to the uremic condition. On the other hand, the accumulation of uremic toxins or other factors relating to the uremic milieu alters multiple metabolic pathways [1]. Derangements in protein and energy metabolism, chronic inflammation, oxidative stress, and hormonal dysfunction ensue due to the uremic condition. The accumulation of phosphorus also affects parathyroid hormone (PTH) and fibroblast growth factor 23 (FGF23), and increased serum levels of PTH and

FGF23 and deficiency of 1,25-dihydroxycholecalciferol and, not uncommonly, 25-hydroxycholecalciferol are present. These humoral factors are the key effectors in CKD—mineral bone disorders. Other hormonal abnormalities include the decrease in the secretion and the actions of growth hormone. Normal growth and development may be hindered in children [2]. The accumulation of nitrogen-containing products from dietary and endogenous protein catabolism may affect taste and smell [2]. Distorted taste and smell lead to appetite loss and further deterioration of nutritional status.

Although large numbers of studies have examined dietary therapy for patients with CKD [3–5], the role of this treatment remains controversial [6]. The Center for Disease Control and Prevention (CDCP) defines the term “prevention” as the activities of three stages: primary prevention, secondary prevention, and tertiary prevention. An Expert Panel of the CDCP proposed and applied these three stages of prevention for the management of CKD [7]. Primary prevention encompasses risk factor management to prevent the development of CKD and cardiovascular disease. Secondary prevention has the goal of slowing CKD progression

and delaying/deferring commencement of renal replacement therapy (RRT). Tertiary prevention aims to manage uremic symptoms and comorbidities.

Traditionally, two major indications for dietary therapy for patients with CKD have been proposed. One indication is to reduce damage to the kidney, thereby decreasing progressive kidney injury and scarring and reducing the rate of progressive loss of kidney function [8]. This indication aims at the secondary prevention of CKD, and the role of dietary protein and phosphorus restriction to slow progression of CKD has been the focus of this goal [8]. The other indication is to reduce the accumulation of potentially toxic compounds in CKD patients and also to prevent or treat protein–energy wasting (PEW) [9,10]. This indication can be viewed as the tertiary prevention of CKD progression. Detailed components of the dietary interventions for these two indications have much in common, but the patients that are addressed by these two interventions differ by the stages of their CKD. The relative interest by the medical community in these two potential roles for the treatment of CKD has varied greatly, at least since the 19th century [11].

### Protein intake

The amount of protein intake affects CKD patients in three ways: the first is that protein intake per se increases the GFR of the failing kidneys; the second is the metabolites derived from the protein ingested may act as uremic toxins, some of which, such as indoxyl sulfate or hydrogen ion, may worsen kidney function; and the third is that foods or food ingredients that contain much protein may also contain excessive amounts of such other solutes phosphate and potassium. Therefore reduction of dietary protein intake has been used to ameliorate the progression of renal failure via such mechanisms as attenuation of hyperfiltration or reduced single nephron hypertrophy induced by the protein load to the failing kidneys or by the reduction in the accumulation of uremic and nephrotoxic substances. In addition, reduction in protein intake by reducing the accumulation of uremic toxins may postpone the time until RRT is required.

Metaanalyses indicate that protein restriction does delay the need for RRT [4,12]. Whether this effect is due, in part, to suppression of the rate of progression of renal disease and loss of GFR or is exclusively the result of a lower rate of generation of uremic toxins is unclear. Even in patients with far-advanced CKD who might commonly be placed on RRT, low-protein diets (LPDs) have been shown to delay the need for chronic dialysis therapy.

Brunori et al. demonstrated this in a randomized, prospective controlled trial that investigated the effectiveness of supplemented very low protein diets (SVLPD) with a mixture of ketoacid and hydroxyacid analogs of five essential amino acids and four other essential amino acids. Predialysis patients without diabetes mellitus who were older than 70 years and had a GFR of 5–7 mL/min were studied [13]. Patients were randomized to either begin maintenance dialysis ( $n = 56$ ) or to receive SVLPD ( $n = 56$ ), which provided 35 kcal/kg/day and 0.3 g/kg/day of protein supplemented with ketoacids or one hydroxyacid, essential amino acids, and vitamins. A total of 40 (71%) of the patients assigned to the SVLPDs started chronic dialysis after 6–20 months of dietary therapy; the patients delayed dialysis initiation by a median period of 10.7 months without evidence of worse outcomes as compared to the group that started dialysis at the onset. A total of 31 (55%) patients died in the dialysis group and 28 (50%) patients in the diet group during a median follow-up period of 26.5 months. Unadjusted survival was not different between the two groups, although after adjustment for the greater age and higher prevalence of cerebral vasculopathy in the SVLPD group, there was significantly greater survival in the diet group by per-protocol analysis but not by intention-to-treat analysis. The number of hospitalizations and days of hospitalization per patient-year were significantly less ( $P < .001$  and  $P = .02$ ) in the SVLPD group, although these differences disappeared if hospitalizations for the placement of the first dialysis access in the diet group were included in these calculations. These findings strongly suggest that dietary therapy can safely delay the need for chronic dialysis for several months in selected pre-ESRD (end-stage renal disease) patients. LPDs or SVLPDs may also provide advanced CKD patients with sufficient time for the placement and maturation of a permanent hemodialysis (HD) vascular access or peritoneal dialysis catheter without requiring the use of temporary catheters needed to inaugurate dialysis urgently.

### Energy intake

The importance of adequate energy intake was shown in a study that investigated nitrogen balance and urea nitrogen appearance in advanced CKD patients who received different energy intakes [14]. A number of 6 nondialyzed patients with advanced CKD [the mean estimated GFR (eGFR) calculated from the mean of the creatinine and urea clearance was  $7.8 \pm 4.3$  SD mL/min] were each assigned to ingest diets providing energy intakes of 25, 35, or 45 kcal/kg/day; the order of administration of these

three energy intakes was determined in random fashion. In addition, two of the patients were assigned diets providing only 15 kcal/kg/day. Dietary protein intake for all patients was 0.55–0.60 g protein/kg/day with all four diets and was constant for each patient throughout the period of their study. Each of the dietary energy intakes was consumed for a mean of  $23.7 \pm 5.7$  SD days. A total of 16 metabolic balance studies were performed on two, five, five, and four patients fed 15, 25, 35, and 45 kcal/kg/day, respectively. Changes in body weight during each study period were determined in two, five, five, and three patients fed an energy intake of 15, 25, 35, and 45 kcal/kg/day, respectively. The study demonstrated that three out of four individuals taking the energy intake of 25 kcal/kg/day showed negative nitrogen balance, while only one of five and four participants had negative nitrogen balance with the 35- and 45-kcal/kg/day energy intakes, respectively. Body weight decreased in two of five patients with 25 kcal/kg/day, while body weight increased in four of five and all three patients who were provided with 35 and 45 kcal/kg/day, respectively. These data indicate that patients with advanced CKD appear to require an energy intake of about 35 kcal/kg/day to maintain neutral or positive nitrogen balance and stable body weight [14]. An animal model of kidney disease demonstrated that a high-calorie diet can ameliorate disturbances of lipid metabolism in remnant kidneys [15].

A post hoc evaluation of the Modification of Diet in Renal Disease (MDRD) study found that the participants randomly assigned to the SVLPD diet experienced an increased risk of death over a 10-year period of follow-up [16]. A total of 49 patients assigned to the SVLPD died (38.9%, 21% due to cardiovascular causes), whereas only 30 patients assigned to the LPD died (23.3%, 16% due to cardiovascular deaths). The hazard ratio (HR) for death was 1.92 (95% CI, 1.15–3.20) in the fully adjusted model. It is not clear how the increased mortality in the SVLPD group could be related to their diet, particularly because the post hoc follow-up was to years and the mean duration of treatment time for the patient on the MDRD protocol was only 2.2 years. Moreover, it would have been very difficult for any patient in the MDRD study to obtain access to the ketoacids-essential amino acid mix once they left the MDRD study.

The MDRD study also indicated that it was not easy to maintain an adequate energy intake on the LPD and SVLPD diets. The patient's energy intake decreased from  $25.0 \pm 6.7$  and  $25.5 \pm 6.5$  kcal/kg body weight (BW)/day at the baseline in the LPD and the SVLPD groups, respectively, to  $21.9 \pm 4.6$  and  $22.0 \pm 4.7$  kcal/kg BW/day during the follow-up period in the LPD and the VLPD groups [16]. The energy intakes in the LPD and SVLPD

patients in the MDRD study were lower than the lowest energy intake in the abovementioned nitrogen balance study, which was 25 kcal/kg/day and did not maintain the nitrogen balance or body weight in nondialyzed advanced CKD patients [14]. These findings suggest that it can be challenging to maintain adequate energy intake with the LPD or SVLPD diets; this reduced energy intake might lead to deterioration in clinical outcomes. Indeed, the patients who were assigned to the LPD or SVLPD diets in the MDRD study lost weight [17].

Many studies have reported that the energy intake of CKD patients in the real world is far less than is recommended. A study investigated 539 patients with stage 3+ CKD in Taiwan and demonstrated that their dietary energy intake was also less than that recommended by dietitians across all CKD stages [18]. Another study obtained similar results. This study, performed in Brazil, investigated the dietary protein and energy intake of 454 participants with reduced kidney functions ( $\text{eGFR } 38.4 \pm 14.6 \text{ mL/min/1.73 m}^2$ ) [19]. The investigators found that the patients' median dietary energy intake was 25.0 kcal/kg/day (IQR, 19.5–33.0 kcal/kg/day) and median protein intake was 1.1 kcal/kg/day (IQR 0.9–1.4 kcal/kg/day).

Efforts have been made to meet the daily energy requirements of patients with CKD [20–22]. The baseline the dietary protein and energy intakes and nutritional markers in the MDRD study were investigated according to the patient's GFR levels [23]. The investigators found that the dietary energy intake was lower than the recommended values, especially in the patients with the lower GFR levels. The amount of dietary energy intake (mean  $\pm$  SD) calculated from interviews by dietitians were  $26.4 \pm 6.90$  ( $P < .01$  vs GFR  $>37$  group),  $29.2 \pm 10.0$  ( $P < .05$  vs GFR  $>37$  group), and  $31.0 \pm 9.30$  kcal/kg/day in men and  $24.6 \pm 8.58$  ( $P < 0.01$  vs GFR  $>37$  group),  $27.9 \pm 8.58$ , and  $27.7 \pm 8.84$  kcal/kg/day in women with GFR levels of  $<21$ ,  $21\text{--}37$ , and  $>37 \text{ mL/min/1.73 m}^2$ , respectively.

A similar trend was observed with regard to the patients' dietary protein intakes. The patients with the lower GFR levels exhibited poorer nutritional measures as compared to those with the higher GFRs. These associations were attenuated after adjustment for the different dietary energy and protein intakes of the patients, which suggests that the poorer nutritional status found in the advanced CKD patients may be due to the decreased dietary intake. It is noteworthy that 657 individuals out of 1785 patients in the study population reported that their protein and/or energy intake was recommended to be reduced [23].

Another question is whether the type of dietary protein influences the ease of maintaining an adequate energy intake with LPDs. This was investigated in six

nondialyzed CKD patients fed two LPDs [about 0.6 g protein/kg ideal body weight (IBW)] that contained either 70% animal protein or 30% animal protein [24]. Daily energy expenditure was estimated from the patient's measured resting energy expenditure and the patient's activity levels. The mean serum creatinine level of the six CKD patients was 300  $\mu$ mol/L. The patients' diet was changed from a conventional LPD providing 70% animal protein to a 30% animal protein diet that was ingested for at least 2 weeks. Total protein intake was similar with both diets,  $0.70 \pm 0.05$  g/kg IBW/day (mean  $\pm$  SD) and  $0.73 \pm 0.11$  g/kg IBW/day ( $P = .638$ ), with the 70% and 30% animal protein diets, respectively. The dietary energy intake increased slightly, from  $27.8 \pm 6.1$  (SD) kcal/kg IBW/day to  $31.4 \pm 7.0$  kcal/kg IBW/day ( $P = .094$ ), when the patients changed from the 70% animal protein diet to the 30% animal protein diet. However, four of six patients eating the 70% animal protein diet and three of six patients ingesting the 30% animal protein did not eat an amount of calories that equaled their calculated daily energy expenditure [24]. Since plant-derived foods are often a major source of dietary protein in CKD patients, protein-free foods may be added to ensure that energy intake is adequate.

### Importance of monitoring the patient

Patients with advanced kidney disease are prone to experience malnutrition and wasting. The International Society of Renal Nutrition and Metabolism has publicized the concept of PEW [25]. PEW is manifested by abnormalities and/or reductions in serum chemistries, body mass, muscle mass, and dietary protein and energy intake. Tools have been described for assessing the presence and severity of PEW; these include appetite, food intake, energy expenditure, body mass and composition, laboratory markers, and nutritional scoring systems [25]. Patients with advanced CKD who are treated with dietary therapy should be repetitively monitored with these markers to assess whether they have developed signs of PEW.

### Serum chemistries

Serum albumin is synthesized by the liver, and its production is affected by nutritional status [26,27], inflammation, and acidemia [28]. Serum albumin has a strong and consistent role in predicting mortality and morbidity, especially in chronic dialysis patients [25]. Several factors affect the serum albumin level in patients with advanced kidney disease in addition to nutritional, inflammatory, and acid–base status. Low

serum albumin levels are associated with the severity of proteinuria in diabetic nephropathy and with the rate of progression of renal disease [29]. An extrapolation from the accumulated evidence in patients undergoing maintenance dialysis [30] suggests that volume expansion or overhydration may also lower the serum albumin level.

Transthyretin is another serum protein that can be associated with the nutritional or protein–energy status of the patient. Little evidence has been obtained regarding the serum transthyretin level as a nutritional marker in CKD patients not on dialysis, although several studies have investigated in dialysis patients [31,32]. A cross-sectional study investigated the association between serum transthyretin and nutritional or protein–energy status, as indicated by body mass index (BMI), in CKD patients with or without RRT [33]. The authors found that a significant positive association between serum transthyretin and BMI ( $r = 0.20$ ,  $P = .02$ ) in the entire cohort, while the C-reactive protein level was negatively associated with the serum transthyretin concentration [33]. The significance of maintaining healthy nutritional or protein–energy status in patients with advanced CKD was illustrated by an observational cohort study that investigated the association between the protein–energy status at the inception of dialysis treatments and patient survival thereafter [34]. This study included 167 incident chronic dialysis patients (HD, 57.5%) and assessed the baseline demographics and such protein–energy indices as BMI, serum albumin, and subjective global assessment (SGA) score. Both a low-serum albumin less than 3.3 g/dL and an SGA score of B and C indicating the presence of PEW were significantly associated with the higher risks of all-cause mortality (HR 1.86, 95% CI 1.17–2.97,  $P = .01$  and HR 1.74, 95% CI 1.11–2.72,  $P = .02$ , respectively) during a median follow-up of 53.0 months (IQR, 23–83 months) [34].

### Body weight

The trajectory of body weight change before initiation of dialysis therapy can be associated with worse outcomes after starting dialysis treatment. A study investigating a total of 3933 patients in the CRIC study and 1067 participants in the AASK study assessed the association between the GFR level and body weight change and between body weight change prior to dialysis and all-cause mortality after the commencement of chronic dialysis. [35]. A similar trend of body weight change was found in both the CRIC and the AASK studies, whereby there was a substantial decline in body weight after the eGFR, estimated from cystatin C and the CKD-EPI equation, decreased to

about 35 mL/min/1.73 m<sup>2</sup>. In the CRIC study, every 10 mL/min/1.73 m<sup>2</sup> further decline in eGFR<sub>crs</sub> was associated with a mean decrease of 1.45 (95% CI, 1.19–1.70) kg in body weight, and a mean decline of 0.31 (95% CI 0.21–0.40) kg/m<sup>2</sup> in BMI. In the AASK study patients, there was a mean decrease in body weight of 2.3 (95% CI, 2.1–2.4) kg, and a mean reduction in BMI of 0.79 (95% CI 0.73–0.86) kg/m<sup>2</sup> for every 10 mL/min/1.73 m<sup>2</sup> decline. During a median follow-up period of 3.3 years (IQR, 1.5–4.8) in 770 participants in the CRIC study, the annual percent weight change between the time when eGFR reached 35 mL/min/1.73 m<sup>2</sup> and the time of initiation of dialysis therapy was significantly associated with the survival rate of the patients. The adjusted HR for mortality for participants who had larger annual declines in body weight of 5% or more per year was 1.54 (95% CI 1.17–2.03) as compared to participants whose annual changes in body weight were between –5% and +5% per year. A similar association between change in body weight and survival was observed in the AASK study (HR 1.56, 95% CI, 1.06–2.30) [35].

Another study including a total of 11,090 nursing home residents examined the association between the body weight changes during the 3–6-month period before the initiation of chronic dialysis and 1-year survival after starting dialysis [36]. This study demonstrated that the median decrease in body weight during this period was –6% (IQR –13%, +1%). Percent body weight change was categorized into quintiles, namely, –59% to 15%, –14% to –9%, –8% to –4%, –3% to 3%, and 4% to 58%. Participants in the first, second, and fifth quintiles of the changes in body weight experienced worse survival as compared to the reference group of the fourth quintile; mortality HRs in the first, second and fifth quintiles of weight change were 1.35 (95% CI 1.25, 1.47), 1.07 (95% CI 1.00, 1.17), and 1.24 (95% CI 1.14, 1.35), respectively [36].

## Composite scores

Several composite scores of protein–energy status and inflammation, including SGA, MIS (malnutrition–inflammation score, also known as the Kalantar score), and MNA (mini nutritional assessment) have been developed to assess the protein–energy status of the patients. These scores have been extensively investigated with regard to their association with clinical outcomes in the dialysis population [37–40]. However, only a limited number of studies have investigated the validity of these composite scores in nondialyzed advanced CKD patients.

A cohort study investigated the association between the protein–energy status, assessed by the four-point

SGA scale, and all-cause mortality during a 5-year follow-up period [41]. A total of 1031 CKD patients (732 nondialysis CKD stage 1–5 patients and 299 chronic dialysis patients) were included in this study. PEW assessed by SGA (PEW<sub>SGA</sub>) was defined as an SGA score of more than 1. A PEW<sub>SGA</sub> was associated with a significantly higher risk of death, with an RR of 1.19 (95% CI, 1.08–1.31, *P* = .0003) and 1.15 (95% CI 1.07–1.23, *P* < .0001) in the nondialyzed and chronic dialysis patients, respectively [41].

Another study investigated the association between the MIS and survival of 300 nondialyzed CKD stage 3–5 patients [42]. A high MIS was significantly associated with an increased prevalence of advanced CKD in these patients (*P* < .001). MIS was also significantly associated with higher risks of death during a median follow-up of 30 (IQR, 18–37) months. The HR for death in 300 patients was 1.09 (95% CI 1.02–1.17) per unit increase in the MIS. Patients in the group with the highest tertile of MIS exhibited a higher risk of death (HR 2.59, 95% CI, 1.31–5.11) compared to the lowest tertile group. The group with MIS > 3 had a HR for death of 1.93 (95% CI 1.07–3.49) compared to the group with MIS ≤ 3 [42].

## Benefit beyond dialysis initiation

Inadequate nutritional intake in patients with advanced CKD is of substantial concern, because PEW is common in patients who are beginning dialysis therapy [43]. In the authors' experience, patients often describe weight loss during the 3–6 months preceding their commencement of chronic dialysis therapy, a finding similar to that reported in nursing home patients starting dialysis [36]. Tortorici et al. observed that a decrease in serum albumin during the months before patients with advanced CKD began chronic dialysis.

These findings are troubling because patients starting chronic dialysis who have PEW have increased mortality [43]. As a result, patients who started dialysis therapy experience worse survival during the first several months (Fig. 30.1). However, substantial data indicate that LPDs and SVLPDs, when properly prescribed, do not engender PEW [10,44]. These findings raise the possibility that properly prescribed dietary therapy in patients approaching ESRD might reduce their mortality risk after they commence chronic dialysis treatment, a thesis that would seem well worth testing [45,46].

The foregoing considerations suggest that LPDs or ketoacid or essential amino acid–SVLPDs may be able to safely delay the need for chronic dialysis therapy by reducing the generation of uremic toxins, independent

**FIGURE 30.1** High mortality rate during the first 12 months of hemodialysis therapy in more than 52,000 incident ESRD veterans in the United States over 4 years (10/2007–9/2011). of whether the rate of decline of GFR is diminished. The clinical trial of Brunori et al. [13] is pertinent in this regard. These investigators showed that selected stage 5 CKD patients with a GFR of 5–7 mL/min who were prescribed SVLPDS could safely delay their need for chronic dialysis therapy.

LPDs (i.e., 0.6 g protein/kg/day) and SVLPDs may also provide patients with advanced CKD with sufficient time for placement and maturation of a permanent HD vascular access or peritoneal dialysis catheter without requiring the use of temporary catheters needed to inaugurate dialysis urgently [47]. Mortality increases when people commence chronic dialysis [48]. Functionality decreases in nursing home residents when they begin dialysis [49]. If these adverse events are related to dialysis treatment per se, this may provide another indication for the use of LPDs and SVLPDs to delay the initiation of dialysis. More randomized, prospective clinical trials (RCTs) are needed to define the roles of dietary therapy for people with far-advanced CKD.

### Dietary therapy for incremental or infrequent dialysis

LPD and SVLPD therapy has another role for patients with advanced CKD who selected incremental or infrequent dialysis (Table 30.1). These dialysis regimens are performed in the schedule with once or twice weekly compared with the ordinary thrice-weekly HD

treatment [50]. Patients whose kidney function has declined to the degree to which chronic dialysis is required but is sufficiently high that standard thrice-weekly HD or daily peritoneal dialysis may not be necessary to minimize uremia may benefit from these regimens [51]. To control uremic toxicity, an attenuated dose of dialysis may be offered to these patients, which will be augmented by the residual renal function (RRF), for example, once- or twice-weekly HD or a similarly reduced dose of chronic peritoneal dialysis (Table 30.2). As RRF, that is, the GFR of the native kidneys continues to decrease while these patients receive incremental dialysis, uremic toxins may accumulate, and the dose of chronic dialysis is progressively increased until the patient is receiving standard doses of chronic dialysis therapy. In practice, many nephrologists simply use infrequent dialysis, wherein the patient receives a rather fixed dose of infrequent dialysis until RRF declines to a degree that signs of uremia begin to become prominent and standard dialysis therapy is instituted (Fig. 30.1).

Clinical trials and epidemiologic studies suggest that this treatment may offer several advantages to the patient. Patients, especially older patients, may find the treatment regimen preferable to a more demanding standard full-dose regimen of chronic dialysis therapy. Incremental or infrequent dialysis may provide patients with the time needed to rearrange their lifestyle appropriately or become more emotionally adjusted to chronic dialysis therapy [52]. Lower or less frequent doses of dialysis seem to delay the decline in

**TABLE 30.1** Nutritional management of incremental hemodialysis (HD): strategies for dialysis commencing from once-weekly to higher frequencies.

	Once-a-week	Twice-a-week	Thrice-a-week
Nutritional support	+++	++	+
Protein intake	Reduced (e.g., 6 out of 7 days): SVLPD	Reduced (e.g., 5 days): SVLPD or LPD	Increased
Energy intake	Increased	Increased	Increased
Vascular access compromise	+	++	+++
Protection of residual renal function	+++	++	–/ +
“Counter-physiologic” effect of HD treatment	+	++	+++
HD scheduling challenge	+	++	–
Costs and reimbursement	+	++	+++

LPD, Low-protein diet; SVLPD, supplemented very low protein diet.

**TABLE 30.2** Proposed decision support system with 11 criteria for initiating and maintaining incremental (twice-weekly) hemodialysis (HD) treatment upon transition to end-stage renal disease, and for incremental transition to thrice-weekly HD.

#### Incremental (twice-weekly) HD treatment criteria

1. Adequate residual kidney function with a urine output >600 mL/day (transition to thrice weekly if urine output drops to <500 mL/day)<sup>a</sup>
2. Limited fluid retention between two consecutive HD treatments with a fluid gain <2.5 kg (or less than 5% of the ideal dry weight) without HD for 3–4 days
3. Limited or readily manageable cardiovascular or pulmonary symptoms without clinically significant fluid overload<sup>b</sup>
4. Suitable body size relative to residual renal function; patients with larger body size may be suitable for twice-weekly HD if not hypercatabolic
5. Hyperkalemia ( $K > 5.5$  mEq/L) infrequent or readily manageable
6. Hyperphosphatemia ( $P > 5.5$  mg/dL) infrequent or readily manageable
7. Good nutritional status without a florid hypercatabolic state
8. Lack of profound anemia (hemoglobin > 8 g/dL) and appropriate responsiveness to anemia therapy
9. Infrequent hospitalization and easily manageable comorbid conditions
10. Satisfactory health-related quality of life and functional status
11. KRU > 3 mL/min/1.73 m<sup>2</sup> (transition to thrice-weekly if KRU < 2 mL/min/1.73 m<sup>2</sup>)

#### Implementation strategies

1. To initiate twice-weekly HD, the patient should meet the first (urine output >600 mL/day) and the last criteria (KRU > 3 mL/min/1.73 m<sup>2</sup>), plus most (five out of nine) other criteria
2. Examine these criteria every 1–3 months in all twice-weekly HD patients and compare outcome measures between twice- and thrice-weekly HD patients to assure outcome noninferiority for continuation of twice-weekly HD
3. Consider transition from a twice-weekly to thrice-weekly HD regimen if patient's urine output drops <500 mL/day, if KRU declines <2 mL/min/1.73 m<sup>2</sup>, or if patient's nutritional status or general health condition shows a deteriorating trend over time

<sup>a</sup>The minimum required urine output to initiate twice-weekly has been changed to 600 mL/day in this adaptation, while >500 mL/day is needed to maintain twice-weekly regimen.

<sup>b</sup>Lack of systolic dysfunction ( $EF > 40\%$ ) and no major coronary intervention over the past 3 months.

residual GFR, improve quality of life, possibly decrease mortality rates, and reduce health care costs [50–54]. In fact, higher levels of RRF are associated with reduced mortality rates in both patients

undergoing chronic peritoneal dialysis and patients receiving chronic HD [55,56]. One epidemiologic study indicated that compared with patients treated with standard thrice-weekly HD, patients with renal urea

**FIGURE 30.2** Transition from advanced chronic kidney disease (eGFR < 30 mL/min/1.73 m<sup>2</sup>) to renal replacement therapy with different modalities, also highlighting intermodality transitions and impact on clinical outcomes.

clearances >3.0 mL/min/1.73 m<sup>2</sup> may survive longer on once-weekly dialysis with a slower loss of RRF; but those with renal urea clearances ≤3.0 mL/min/1.73 m<sup>2</sup> may have greater mortality [50]. These findings indicate that the RRF and incremental dialysis are mutually interdependent. Incremental dialysis may preserve RRF, and RRF itself is indispensable for the clinical benefits of incremental dialysis.

Two metaanalyses were performed that compared incremental dialysis, including HD or peritoneal dialysis, with conventional full-dose dialysis. One metaanalysis, including 11 observational cohort studies, was performed on patients receiving incremental HD or peritoneal dialysis in comparison with the standard, full-dose dialysis [57]. This study investigated the associations between these dialysis modalities and all-cause mortality, RRF loss, and time to full-dose dialysis. Incremental dialysis was not significantly associated with any higher risk of all-cause mortality (HR, 1.14, 95% CI 0.85, 1.52). Moreover, the loss of RRF was smaller or RRF was more preserved with incremental dialysis as compared with patients on full-dose dialysis; the decline in RRF was −0.13 (95% CI, −0.18, −0.08) and −0.74 (95% CI, −1.15, −0.33) mL/min/month in incremental dialysis and full-dose dialysis, respectively. The mean difference between the two groups was 0.58 (95% CI, 0.16, 1.10) mL/min/month in the random-effects model ( $P = .007$ ). The overall mean time to full-dose dialysis was 12.1 months (95% CI 9.8, 14.3) with a random effects model [57] (Fig. 30.2).

The other metaanalysis investigated the effects of incremental HD, as compared to standard HD, on

mortality, renal function, urinary volume, and laboratory measures [58]. The study included 15 observational studies and one cross-sectional study. The group receiving incremental HD had greater survival (RR, 0.80, 95% CI 0.73, 0.87,  $P < .001$ ,  $I^2 = 0\%$ ), better preservation of renal function (standardized mean difference: 0.68, 95% CI 0.04, 1.32,  $P = .039$ ,  $I^2 = 92.7\%$ ), and urinary volume (weighted mean difference: 333.4, 95% CI 86.8, 579.9,  $P = .008$ ,  $I^2 = 92.7\%$ ). The low  $I^2$  values indicate that in these studies the heterogeneities were low with regard to survival but were considerably higher with regard to the preservation of renal function and urinary volume. The metaanalysis also compared serum calcium, phosphorus, albumin, and blood hemoglobin at the end of the follow-up period or the changes in these measures between the beginning and the end of follow-up in the patients receiving incremental HD versus full-dose HD. The laboratory measurements did not differ between the two groups, except for the serum calcium levels and blood hemoglobin levels at the end of the follow-up period, which were lower to a small but statistically significant degree in the incremental HD group. Hospitalization also did not differ between the groups [58]. Patients receiving incremental dialysis seemed to have their uremic symptoms mitigated as much as patients receiving standard dialysis therapy [51]. Unfortunately, the protein intake was not investigated or compared in these metaanalyses, although Garofalo et al. described a renal replacement regimen consisting of once-weekly HD combined with a dietary intervention consisting of a low protein, low phosphorus, and high-energy diet. They also

discussed the importance of utilizing dietary and pharmacological therapy to augment the effectiveness of incremental RRT [57].

Because well-designed LPDs and SVLPDs will reduce the load of many potentially toxic solutes that accumulate in kidney failure, the combination of incremental dialysis and dietary therapy may provide ESRD patients who have substantial RRF with the benefit to safely delay standard dialysis therapy. Indeed, some investigators have combined once- or twice-weekly dialysis with well-defined dietary management LPDs or SVLPDs [52,53,59,60].

Locatelli et al. investigated the effects of the integrated diet dialysis program on its feasibility, its effect on nutritional status, and the removal of solutes and water [52]. The program consisted of a dietary intervention with an LPD (0.4 g/kg IBW/day) supplemented with essential amino acids or a mixture of essential amino acids and ketoacid analogs combined with once-weekly HD. The goal was to maintain the predialysis serum urea level below 90 mg/dL (i.e., a predialysis serum urea nitrogen, SUN or BUN, level below 42 mg/dL). The mean baseline GFR was  $2.54 \pm 0.94$  mL/min. The patient and technical survival rates were 89% and 56%, respectively, at the end of the 12-month follow-up period. Protein–energy factors, including body weight, lean body mass, fat mass, plasma proteins, albumin, transferrin, and C3 and C4 complement components, remained stable throughout the follow-up period, although the creatinine appearance rate and nerve conduction velocities were decreased at the end of the follow-up period [52].

In another more recent multicenter, nonrandomized, prospective controlled study of 68 incident CKD patients with a GFR between 5 and 10 mL/min/1.73 m<sup>2</sup> who were followed in predialysis clinics, a combination of infrequent HD and an LPD (a Combined Diet Dialysis Program, CDDP) was compared to a standard thrice-weekly HD schedule and free-choice diet (the THD group) [53]. The CDDP consisted of a weekly HD schedule and an LPD (0.6 g/kg/day) with adequate energy (30–35 kcal/kg/day) and low phosphorus (600–700 g/day), and low sodium that was fed on the nondialysis days. Patients in the CDDP group ( $n = 38$ ), as compared to the THD patients ( $n = 30$ ), maintained greater urinary output and RRF after 12 months and had a lower erythropoietin resistance index, a lower  $\beta_2$  microglobulin level, stable protein–energy status, and a lower need for cinacalcet and phosphate binders. The survival rate in the CDDP patients was similar to the THD group, whereas the hospitalization rate was lower in the CDDP patients than in the THD group during a follow-up period of 24 months [53].

The result of this study indicates that some but not all patients treated with diet and incremental dialysis

are able to safely delay their need for standard dialysis treatment. Although HD may cause catabolic, inflammatory, and hemodynamic stresses, LPDs and SVLPDs seem to maintain good protein–energy and metabolic and clinical status and result in a slower loss of RRF [53,59,60], possibly because HD is performed less frequently. The required dose of ESA may decrease because infrequent HD lessens the loss of blood [53]. Blood loss due to HD treatment can be substantial. Strongly motivated patients who are more knowledgeable about CKD seem to adjust better to this diet and infrequent dialysis regimen [52,53].

LPDs or SVLPDs are not uncommonly prescribed with these dialysis regimens. However, the extent to which the apparent benefits of incremental or infrequent dialysis are due to or require treatment with these diets is not known. Indeed, there are no RCTs that compare outcomes with either incremental or infrequent dialysis with those of standard thrice-weekly HD or that compare incremental dialysis with LPDs or SVLPDs with incremental dialysis without such diets. RCTs are needed to confirm whether incremental or infrequent dialysis does induce these benefits and the degree to which LPDs or SVLPDs contribute to the apparent benefits of less frequent dialysis. In some studies of incremental dialysis, the frequency or dose of dialysis was not increased as the GFR continued to fall. This latter type of treatment should probably be considered to be infrequent dialysis rather than incremental dialysis.

### Future directions

The CKD patients who are more likely to benefit from LPDs and SVLPDs, and the level of reduced GFR at which these diets should be implemented, need to be better defined. Randomized controlled clinical trials should help in this regard. One approach would be to prescribe these diets with incremental dialysis when it is considered time to start maintenance dialysis therapy. Such dietary therapy could be integrated into a more general plan for the nutritional management of CKD patients since the authors believe that a strong case can be made to start some form of dietary therapy at substantially higher GFRs. This is particularly the case for controlling sodium, potassium, phosphorus, and calcium balance and maintaining adequate energy intake so as to prevent PEW. Protein restriction at higher levels of GFR may also ameliorate more subtle uremic symptoms. Current data suggest that patients need a minimum GFR level—possibly a urea clearance  $\geq 2$ –3 mL/min/1.73 m<sup>2</sup>—to do well with dietary therapy [46]. Patients being considered for dietary therapy probably should not suffer from severe acute or

chronic catabolic illness, should be able to understand the purpose and potential benefits of dietary therapy, should have self-discipline, and should be strongly motivated. This review does not address the question of whether dietary therapy can retard the progression of kidney failure.

We need a clearer understanding of the extent to which dietary therapy will maintain both pre-ESRD and ESRD patients in good nutritional and metabolic status, safely prevent and ameliorate various manifestations of uremia, and, thereby, delay the need for RRT independent of any effect on the rate of decline of GFR. The optimal intake of protein, amino acids, and other needed nutrients for these patients needs more careful definition. The role of LPDs and SVLPDs for patients receiving incremental or infrequent dialysis requires more investigation, particularly with regard to defining patients who are good candidates for such treatment, optimal dietary therapies for this regimen, and techniques for increasing dialysis treatment as RRF declines. Whether intestinal sorbents or binders (e.g., activated charcoal to bind indoxyl sulfate) can safely and effectively augment dietary management also needs investigation [61].

Another challenge is improving the patient's adherence to dietary therapy. Aparicio et al. [20] observed that about 50% of patients with CKD adhere satisfactorily to SVLPDs. This may be an overly optimistic estimate for the general CKD population, perhaps due to the types of patients referred to Aparicio et al. [20] and their clinical expertise. However, for pre-ESRD and ESRD patients, the prospect of commencing chronic dialysis therapy or undergoing more frequent (i.e., standard dose) dialysis often engenders much anxiety, which may increase the patients' motivation for dietary adherence. Clearly, not every patient with CKD will adhere to LPDs or SVLPDs.

Finally, it would be of value to improve the training of nephrologists concerning the nutritional management of CKD and to provide the convincing evidence to nephrologists that some dietary therapies can benefit patients with CKD. The ease with which nephrologists can provide nutritional therapy might be facilitated. The National Health and Nutrition Examination Survey data indicate that American men and women with stage 4 or 5 CKD have mean protein intakes of 1.03 and 0.99 g protein/kg IBW/day, respectively, which is substantially greater than currently recommended intakes [62]. This probably reflects, in part, the reluctance of nephrologists to prescribe protein restriction. One solution for this reticence might be to develop centers of excellence for nutritional therapy staffed by renal dietitians. Physicians could easily and with minimal effort refer patients with stage 4 or 5 CKD

to these centers. Such centers could be economically feasible, at least in urban areas with larger population densities. Clearly, more research is required to examine these possibilities and clarify the potential uses of nutritional therapy for patients with far-advanced CKD.

### Introduction

#### Causes of protein-energy wasting in maintenance hemodialysis patients

##### **Factors altering nutrient intake**

The ability of a patient to consume a sufficient diet is often impaired in maintenance hemodialysis (MHD) patients due to reduced appetite [1–3]. This problem is fairly common in MHD patients. As many as 30%–50% of end-stage renal disease (ESRD) and MHD patients are reported to have anorexia. Protein and energy intakes are reduced. A number of studies show that measures that estimate protein and energy stores, muscle mass, fat mass, and serum cholesterol and albumin levels are robust predictors of survival in MHD patients. Remarkably, the energy intake in MHD patients is commonly reduced even more than what has been observed in sedentary individuals. A cross-sectional study in 331 MHD patients showed that 38% of these patients reported reduced appetite [3]. The reports of reduced appetite were associated with a statistically significant decrease in the protein equivalent of total protein nitrogen appearance (PNA) also referred to as protein catabolic rate (PCR). This study also showed that a reduced appetite is associated with markers of poor nutrition, such as reduced adequate protein and energy intake. Inadequate nutrient intake in MHD patients, therefore, is the single most

serum levels of prealbumin (transthyretin), total cholesterol, and total iron-binding capacity (TIBC). Inflammatory markers such as serum interleukin-6 (IL-6), C-reactive protein (CRP), and tumor necrosis factor alpha (TNF- $\alpha$ ) were increased. The MHD patients in this study with reduced appetite required higher doses of erythropoietin, reported lower quality of life, as measured by the SF-36 scoring system, and had increased mortality [3].

There are a multitude of reasons why MHD patients are susceptible to protein-energy malnutrition or the more general syndrome, protein-energy wasting (PEW). The diet of MHD patients is often very restrictive. Because MHD patients are at increased risk for salt and water gain, and hyperkalemia and hyperphosphatemia; these patients are generally prescribed low sodium, potassium, and phosphorus intakes which make their diets more restrictive and less palatable. The frequent presence of diabetes mellitus (DM) among MHD patients (55% in some studies) often makes the prescribed diet even more restricted. The difficulties for these patients to procure and prepare the foods for the prescribed diet because of physical, mental, or financial limitations and the effort involved in procuring and preparing these foods often make it difficult for the MHD patient to ingest the appropriate diet and, hence, to maintain an important factor in the development and maintenance of PEW.

### **Loss of nutrients during hemodialysis**

Loss of amino acids during hemodialysis (HD) has been examined by several investigators and is estimated to be approximately between 4 and 8 g during an HD session [4–6]. In fasting patients, Kopple et al. reported free amino acid losses of 4.5–7.7 g per HD session using a Kiil dialyzer with a glucose-free dialysate for 11 hours. Additionally, an average of 3.7 g (2.4–5.2 g) of bound amino acids (e.g., peptides) were lost into the dialysate. The loss of free amino acids increased to about 5–8 g per HD if these patients were fed during HD. When patients were dialyzed with dialysate containing a glucose concentration of 450 mg/dL (405 mg/dL of anhydrous glucose), there was a reduction in the free amino acid losses. With this glucose in the dialysate, free amino acid losses were 3.3 g in the fasted state and 6.0 g in the nonfasted states. Gutierrez et al. were not able to confirm that the addition of glucose to dialysate reduced amino acid losses [7]. However, Gutierrez et al. used a fairly standard dialysate glucose concentration of 180 mg/dL. Baxter cellulose acetate and Gambro GFS plus 20 hemodialyzers were used. Amino acid losses were  $8.3 \pm 0.9$  SEM g and  $7.9 \pm 0.4$  g with glucose and glucose-free dialysate, respectively. The difference may be due to the fact that the dialysate glucose, probably glucose monohydrate, concentration was only 180 mg/dL which would result in almost no uptake of dialysate glucose into the patient, whereas in the study of Kopple et al. with a dialysate glucose of 450 mg/dL, a substantial amount of glucose uptake by the patients would be anticipated.

Wolfson et al. reported free amino acid losses of  $8.2 \pm$  SD 3.1 g of free amino acids during a 5-hour HD session with a 1.5-m<sup>2</sup> hollow fiber dialyzer or 1.0- or 1.5-m<sup>2</sup> parallel plate dialyzers [5]. Amino acid losses increased, but only minimally, to  $12.6 \pm 3.6$  g when patients were administered intravenous infusions of 39.5 g of amino acids and 200 g of d-glucose monohydrate during the HD. Hence, contrary to some concerns, the great proportion of infused amino acids is retained during an HD treatment.

Ikizler et al. used three different types of dialyzer membranes and examined amino acid losses during HD in MHD patients [6]. About 1 hour prior to HD, a small meal was taken. Patients undergoing MHD with high-flux polysulfone membranes lost  $8.0 \pm 2.8$  g of amino acids per dialysis session. Patients who underwent HD using low-flux polymethylacrylate membranes lost  $6.1 \pm 1.5$  g of amino acids. Those dialyzed with cellulose acetate membranes lost  $7.1 \pm 2.6$  g of amino acids. These small differences in amino acid losses are biologically insignificant and are likely due to variations in blood flow rates and dialyzer surface area.

Protein losses during HD are very small. However, HD with high-flux polysulfone dialyzers (HFPS) with

multiple reuses after bleach and formaldehyde treatments resulted in marked loss of proteins. Ikizler reported that after the sixth reuse of the HFPS, albumin losses became apparent [6]. While the albumin loss with the 15th use was  $1.5 \pm 1.3$  SD per HD, by the 20th use it increased to  $9.3 \pm 5.5$  g. A study by Kaplan et al. reported similar results [8]. Since these reports, polysulfone membranes have been manufactured differently to make them much more resistant to bleach.

Other factors that contribute to protein losses are leaking or clotted dialyzers, loss of blood that occurs with blood sequestration in the dialyzer (5–10 mL usually), blood loss from needle puncture sites and lab draws. These factors could account for 0.6–1.6 g of lost protein during a dialysis session [9].

Metabolic acidemia must be corrected as it has been shown to increase bone resorption and promote protein catabolism. Metabolic acidosis is highly prevalent (e.g., low serum bicarbonate before dialysis) in MHD patients [10–13]. The National Kidney Foundation Kidney Disease Outcomes Quality Initiative (KDOQI) Clinical Practice Guidelines recommend that serum bicarbonate concentrations should be maintained at 24–26 mEq/L [14]. Since some data suggest that even mild acidemia or low-normal arterial blood pH may be associated with negative nitrogen balance, we recommend maintaining the arterial blood pH at about 7.38–7.40 or the serum bicarbonate at around 24–25 mEq/L [15].

HD itself can be catabolic. Gutierrez et al. sham dialyzed ESRD patients with Cuprophane dialyzers (no dialysate used) and showed enhanced release of amino acids [16,17]. This amino acid release was not observed if these individuals were pretreated with prostaglandins, which suggests that prostaglandins may be involved in the genesis of dialysis-induced catabolism. Borah et al. reported data suggesting that HD induces catabolic state [18]. It is important to note that the nitrogen balance studies of Borah et al. were short term, and sufficient time was not allowed for equilibration after changing the dietary protein intakes.

Dialyzer membranes that are not adequately biocompatible can induce the release of proinflammatory cytokines (e.g., TNF- $\alpha$ , IL-1, IL-6, and others) by the activation of complement and leukocytes [19–21]. These proinflammatory cytokines can induce protein catabolism [22–24]. Oxidative stress may also play a role in the activation of the inflammatory cascade in MHD patients. Robust evidence indicates that inflammation is a cause of a hypercatabolic state in MHD patients [25]. Inflammation has been reported to play a central role in the malnutrition–inflammation–atherosclerosis syndrome [26]. Others have suggested that anorexia, inadequate nutritional intake, nutrient losses, and inflammation cause the PEW syndrome. PEW itself may promote inflammation, although clear evidence of this is

lacking. The malnutrition–inflammation complex syndrome is one of the causes of PEW. Other causes of PEW include reduced nutrient intake, nutrient losses into hemodialysate [and occasionally into urine in MHD patients with substantial residual renal function (RRF)], increased circulating levels of some catabolic hormones (e.g., parathyroid hormone, glucagon) and resistance to anabolic hormones [e.g., insulin, growth hormone (GH), insulin-like growth factor-I (IGF-I)], acidemia, and carbonyl stress (see [Chapter 13: Causes and Treatment of Protein-Energy Wasting in Kidney Disease](#)) [27–29].

Other macro- and micronutrients may be lost during HD in addition to the removal of protein and amino acids. Gutierrez et al. found that during HD with glucose-free dialysate, about 26 g of glucose were removed [7]. When dialysate containing glucose (glucose monohydrate, 180 mg/dL) was used, about 30 g of glucose was absorbed. Similar results were reported by Wathen et al. [30]. Losses of water-soluble vitamins during HD are not large because the plasma concentrations of the vitamins are not high, the molecular weights of vitamins often are not small, and, in the case of vitamin B12, it is protein bound. Losses into dialysate may still be substantial for vitamins B1 (thiamin), B2 (riboflavin), B6 (pyridoxine), ascorbic acid, and folic acid [31–33]. Vitamin losses by MHD should easily be replaced by food intake and supplements as long as patients are eating well. Loss of vitamins via urine is negligible in MHD patients.

### The importance of diet and PEW as patients approach and commence maintenance hemodialysis

At the time of initiation of MHD, the protein-energy status of the patient is a predictor of the patient's protein-energy status 1 or 2 years later [34–36]. Therefore it is important to monitor and prevent malnutrition from occurring before the inauguration of MHD. Protein-energy status may undergo improvement with the initiation of dialysis, but this similarity of the protein-energy status at the initiation of MHD to protein-energy nutrition status 1 or 2 years later remains true. Particularly in the predialysis stage [chronic kidney disease (CKD)-5], patients can become frankly anorectic and undergo deterioration in their clinical and nutrition status. It is, therefore, important to ensure a smooth transition to MHD from CKD stage 4 or 5. The NKF KDOQI guidelines recommend the initiation of chronic dialysis in individuals with advanced CKD if their nutritional status is not optimal and is due to uremia [14]. Patients with chronic renal failure (e.g., glomerular filtration rate <15–20 mL/min) who are not responding to vigorous attempts to optimize their

protein and energy intakes and for whom there is no apparent cause for PEW other than low nutrient intake, the initiation of maintenance dialysis or treatment with a renal transplant is recommended.

### Assessment of nutritional status in maintenance hemodialysis patients

Markers of nutritional and protein-energy status predict outcomes in dialysis patients, and, therefore, an assessment of nutritional and protein-energy status should be done at the initiation of dialysis as well as at monthly intervals (see [Table 31.1](#)). Predialysis serum albumin and creatinine, and body mass index (BMI) are independently associated with survival [37]. Data from the US Renal Data System (USRDS) and from large dialysis organizations concerning serum albumin and BMI confirm these findings [38]. In the Canada–USA (CANUSA) study, serum albumin and subjective global assessment (SGA) were independent predictors of death [39].

KDOQI guidelines recommend an assessment of nutritional status in MHD patients with a combination of measures rather than a single measure (see [Table 31.1](#)) [14]. Different aspects of protein-energy status are captured by utilizing measures of energy and protein intake, visceral protein pools, muscle mass, and dimensions of body composition. The effect of using the adjusted body weight [i.e., the patient's actual body weight adjusted for the standard body weight as determined by National Health and Nutrition Examination Survey (NHANES) 3] on clinical outcomes is not well defined [40]. [Table 31.1](#) shows a list of parameters and tools to evaluate nutritional status and the time intervals for assessment as recommended by the KDOQI guidelines [14].

There are three categories in the KDOQI nutritional assessment guidelines. The first category includes measurements that should be routinely performed in all MHD patients. Examples are serum albumin and postdialysis body weight which should be measured monthly. Body weight as a percentage of standard body weight can be measured every 4 months. Because body weight and lean body mass may change and decline in MHD patients, it is important to compare these measurements to previous values [41,42]. There are no specific recommendations regarding BMI, but due to the ease of calculation it should be measured on a monthly to quarterly basis. Although BMI is a better measurement of body mass than body weight alone, both of these measures may be difficult to interpret because MHD patients frequently do not attain normal body water and sodium content postdialysis. Trends in body weight combined with simultaneous

measurement of interdialytic weight gain (IDWG) and volume should be monitored. Because advanced CKD patients and chronic dialysis patients frequently have an abnormal body water content, the BMI may not be a good metric to estimate fat mass and its distribution unless the patient is very obese.

The threshold for BMI at which PEW can be diagnosed is not well defined. The International Society for Renal Nutritional and Metabolism (ISRNM) consensus paper recommended that a BMI < 23 kg/m<sup>2</sup> can be used as an indicator for PEW in the dialysis population, although the relation between BMI and clinical outcome can be affected by race and ethnicity [29,43,44]. In many patients, a BMI of 23 kg/m<sup>2</sup> or lower may not indicate a pathological condition. In cross-sectional studies, anthropometric measurements (waist-to-hip ratio and skinfold thickness) have been found to be more accurate than BMI for identifying CKD patients with obesity. Mid-arm muscle circumference estimates muscle mass. The skinfold thicknesses at several areas in the body, including the triceps or

biceps areas, can be used to estimate body fat. These quantitative anthropometric measurements (mid-arm muscle circumference and skinfold thickness) can be considered good indicators of PEW when they are below the 25th percentile of the values of well-nourished MHD patients [45]. For accuracy, anthropometry is best done by meticulous, experienced personnel with reliable equipment. Changes in dry weight has been correlated to relative risk of all cause death (Fig. 31.1).

The ISRNM panel recommends that a loss of 5% or more of edema-free body weight within 3 months or unintentional weight loss of 10% of edema-free body weight over 6 months indicates PEW independent of weight for height measures [29]. For routine overall assessment, the conventional version of SGA [47–51] and/or its new derivatives, such as the Malnutrition–Inflammation Score [52], should be evaluated twice-yearly. The Geriatric Nutritional Risk Index has been tested in MHD patients but remains a research tool at this time [53,54].

FIGURE 31.1 Association of change in dry weight over 6-months and 5-year mortality in 88,729 MHD patients [46]. MHD, Maintenance hemodialysis. The obesity paradox and mortality associated with surrogates of body size and muscle mass in patients receiving hemodialysis. *Mayo Clin Proc* 2010;85(11):991–1001.

The second category in the KDOQI nutritional assessment guidelines includes measures which help confirm or extend data obtained from the first category. Serum prealbumin (transthyretin) which, like serum albumin, is a negative acute phase protein has a strong association with mortality and hospitalization [55–57]. Dual-energy X-ray absorptiometry (DEXA) [58–60] is the recommended technique to assess body composition according to the KDOQI guidelines, although such alternative methods as bioelectrical impedance analysis (BIA) [61] and near infrared reactance (NIR) [62] can be very useful. DEXA was originally developed to measure bone density but has been adapted to measure fat and fat-free mass and soft tissue composition. DEXA provides minimal radiation exposure and can be completed within 5–15 minutes, which makes it suitable to use serially to monitor changes over time. BIA is performed by applying a small electrical current to a patient and measuring the resistance and reactance to the current. The ratio of resistance to reactance is used to derive total body mass. Total body water is derived from empirical equations. Phase angle measurement, which is a geometric derivative of the ratio of resistance to reactance, correlates strongly with serum albumin levels and anthropometric measurements of protein-energy status. Mushnick et al. showed that low phase angle measurements are associated with increased mortality [63] in chronic peritoneal dialysis (CPD) patients. BIA is best done (more reliably reproducible) within 2 hours after the end of a dialysis treatment in MHD patients [64]. But it has been recommended that BIA should not be done

immediately after the completion of HD but rather about 30–60 minutes after completion. These energy beam–based methods of protein-energy assessment (DEXA, BIA, and NIR) have not yet been proven to improve clinical outcomes in MHD patients and may not be clinically superior to the simpler and less expensive tools as listed in category 1 in Table 31.1.

The third category in the KDOQI nutritional assessment guidelines includes measurements that are generally performed for other clinical purposes, but which if low values are found might suggest the need for a more rigorous examination of nutritional status. These measures include serum creatinine, urea and cholesterol concentrations, and the creatinine index (see Table 31.1). Recent studies have shown strong associations between serum TIBC, which is a reliable indicator of transferrin, and SGA and between both of these measures and clinical outcomes [65].

To be sure, many nonnutritional factors can affect the indicators in this third category. Serum TIBC is influenced by inflammation and, therefore, is not recommended by KDOQI as a measure of protein wasting. Apart from nutritional factors, either albumin synthesis or serum albumin is also affected by body losses of albumin, inflammation, acidosis, acute illness, and hydration status [66–68]. Serum albumin, prealbumin, and TIBC are negative acute phase reactants [68]. The dose of dialysis and magnitude of RRF can affect serum urea and creatinine. A number of epidemiological studies show that these common laboratory measures are strong predictors of hospitalization rates and mortality.

Dietary history, often obtained only for the previous 3 days, by a reliable and well-trained dietician or dietetic technician can also provide a valuable estimate of patient's intake of protein, energy, and other nutrients, particularly if these interviews are combined with a patient's diary of his/her food intake during this same period. Dietary diaries and interviews are time-consuming but can provide information of clinical value. Self-administered food frequency questionnaires (FFQs) may be used to estimate dietary intake in MHD patients. These questionnaires are not very precise and tend to underestimate food intake. Their main value may be to indicate what foods a patient may often, uncommonly, or never eat. FFQs are limited to epidemiological studies at this time.

The ISRNM has advanced a similar panel of assessment tools to screen for and diagnose PEW (Table 31.2). Biannual measurements of serum lipids are recommended because an increasing number of MHD patients, particularly those who have DM, have elevated serum lipids. In patients not taking cholesterol-lowering medications, very low serum cholesterol concentrations are a strong predictor of poor outcome in MHD patients [69,70].

TABLE 31.2 Additional recommended measures for monitoring nutritional and metabolic status of maintenance hemodialysis patients.

IV. Additional measures and tools	• Serum calcium, phosphorus, and Ca-P product	• Monthly
	• Serum potassium	• Monthly
	• Serum bicarbonate, anion gap	• Every 3 months
	• Serum TIBC or transferrin, iron saturation ratio	• Monthly
	• Serum ferritin	• Every 3 months
	• Lipid panel: total cholesterol, triglyceride, LDL and HDL cholesterol	• Every 6 months
	• Serum C-reactive protein <sup>a</sup>	• Every 3–6 months
	• Plasma total homocysteine	• Every 12 months

<sup>a</sup>Other serum markers that may increase during inflammation include interleukin-6 (IL-6), IL-1 $\beta$ , and tumor necrosis factor alpha (TNF- $\alpha$ ).  
HDL, High-density lipoprotein; LDL, low-density lipoprotein; TIBC, total iron-binding capacity.

As shown by Bergstrom et al. and others, elevated serum CRP levels will help identify patients who have inflammation [71]. CRP is an acute phase reactant that increases with inflammation and correlates negatively with serum albumin levels. To identify patients with inflammation, we recommend that serum CRP be measured every 3–4 months, preferably in every MHD patient. Serum CRP levels vary widely in MHD patients, and, therefore, one measurement of serum CRP may not be helpful. Serial measurements are of greater utility. Alternatively, if a patient has low serum albumin or prealbumin, the CRP may be measured to confirm whether an inflammatory state is present. Although both high and low plasma homocysteine levels are associated with poor outcomes in MHD patients, it is not a readily available measurement clinically, and it is not clear what measurements of homocysteine will add to the information that is obtained from the more commonly measured proinflammatory proteins [72–74].

### Protein intake, nutritional status, urea kinetics, protein nitrogen appearance, and its relation to adequacy of dialysis

Measurement of protein intake in MHD patients can be based on the rise of urea nitrogen between two HD sessions, the urea generated during the latter HD session, and the 24-hour urinary excretion of urea, if the patient is not anuric. The urea nitrogen appearance and, hence, the PNA or PCR can be estimated from these urea kinetic measurements. PNA (PCR) reflects net protein degradation, which is the difference between the quantity of protein catabolized and the amount of protein synthesized per day. For a patient who is metabolically stable (i.e., no net protein accrual or loss), PNA (PCR) reflects the amount of his/her protein and amino acid intake each day. PNA or PCR

is expressed as net grams of protein degraded per day. It is often normalized to the patient's body weight (nPNA or nPCR) and is expressed as grams protein/kg/day. nPNA (nPCR) can also be estimated from KT/V (index of urea removal during dialysis) and the average serum urea nitrogen (SUN).

Several studies reported a correlation between adequacy of dialysis, defined by KT/V<sub>urea</sub>, and dietary protein intake as estimated by nPNA (nPCR) [75–77]. Many of these studies were not prospective or randomized, and, therefore, firm conclusions cannot be drawn. Underdialyzed patients are often uremic and anorexic and may have a low nPNA. Delivering a higher dose of dialysis to attain a higher KT/V often ameliorates appetite and increases protein intake [76–78]. A direct correlation between KT/V and PNA was shown in a prospective randomized study by Lindsay et al. [78]. When the KT/V was increased from  $0.82 \pm 0.19$  (SD) to  $1.32 \pm 0.21$  for 3 months, the PNA rose in the experimental group from an initial value of  $0.81 \pm 0.09$  g/kg/day to  $1.02 \pm 0.15$  ( $P = .005$ ), whereas it did not change in the control group. These studies suggest that increasing the dose of HD from a Kt/V of 0.6 to 1.5–1.6 will increase the dietary protein intake in MHD patients. Harty et al. suggested that it is mathematical coupling that is the underlying reason for this effect, because the two parameters are obtained from the same plasma pre- and postdialysis measurements and are also both normalized to body size [79]. However, even when dialysis dose is not normalized to body size and protein intake is not estimated from urea kinetics, for example, if protein intake is estimated by dietary histories in continuous ambulatory peritoneal dialysis patients, several authors still report a significant correlation between dialysis dose and dietary protein intake [80–83].

Epidemiological studies suggest that a decline in protein intake (measured by nPNA or nPCR) may be associated with increased mortality in MHD patients

FIGURE 31.2 Association of estimated dietary protein intake (reflected by nPNA or nPCR) and 2-year mortality risk in 53,933 MHD patients. MHD, Maintenance hemodialysis; nPCR, normalized protein catabolic rate; nPNA, normalized protein nitrogen appearance. Source: Adapted from Shinaberger CS, Kilpatrick RD, Regidor DL, et al. Longitudinal associations between dietary protein intake and survival in hemodialysis patients. *Am J Kidney Dis* 2006;48(1):37–49.

[36,84]. In a longitudinal study of 53,933 MHD patients, the relation between nPNA and all-cause and cardiovascular mortality was examined over 2 years [36]. The greatest survival in the MHD patients was associated with an nPNA between 1.0 and 1.4 g/kg/day, whereas nPNA of <0.8 was associated with greater mortality (Fig. 31.2). Decreased protein intake, as measured with nPNA (range of nPNA was 0.8–1.2 g/kg/day) during the first 6 months of initiation of MHD, was associated with an incrementally greater risk of death over the subsequent 18 months [36]. Hence, an increase in nPNA was associated with trends toward reduced death risk. The Hemodialysis (HEMO) study on the other hand did not show a correlation between nPNA and mortality once serum creatinine and serum albumin levels were controlled for.

The correlation between  $Kt/V_{urea}$  and PNA is not precise [76–78]. Many patients with relatively high  $Kt/V_{urea}$  (>1.5 for HD) have a very low PNA and, hence, reduced dietary protein intake. Independent of the uremic status of some patients, reduced protein intake can occur due to many different comorbid conditions. Patients with severe PEW often have reduced body weight and, therefore, for a given dialysis dose, tend to have higher  $Kt/V_{urea}$ , even though they may eat poorly [85]. There are currently no data as to what extent the  $Kt/V_{urea}$  affects dietary energy intake. Total 122 MHD patients who met the minimum requirements for dialysis adequacy ( $Kt/V > 1.20$ ) over the first 3 months of the observation period, independent of their RRF, showed a strong association between nPNA and subsequent hospitalization and mortality rates [86]. In this

latter study the actual delivered  $Kt/V$  ranged from 1.23 to 2.71 ( $1.77 \pm 0.34$  SD) and nPNA ranged from 0.5 to 2.15 ( $1.13 \pm 0.29$  g/kg/day). The nPNA and  $Kt/V$  did not correlate significantly ( $r = 0.09$ ) except when the analysis was limited to  $Kt/V < 1.5$  ( $r = 0.54$ ) (see Fig. 31.3). Serum albumin levels and nPNA are the only variables that showed statistically significant correlations with hospitalization rates and mortality. These data suggest that protein intake tend to affect clinical outcomes in MHD patients, even among those who receive adequate doses of dialysis. The tight correlation between  $Kt/V$  and nPNA does not hold once  $Kt/V$  is >1.50. To confirm these conclusions, randomized prospective trials in MHD patients fed different protein intakes will be required.

It is recommended that MHD should receive a dialysis dose, measured by  $Kt/V$ , of at least 1.20 and the optimal goal is for an nPNA (nPCR) >1.4 g/kg/day. In many dialysis facilities, it is difficult to attain a  $Kt/V$  of at least 1.20. The HEMO study failed to show an improvement in hospitalization or mortality with  $Kt/V$  (single-pool) values of  $1.71 \pm 0.11$  SEM compared to  $1.32 \pm 0.09$ , but a number of epidemiological studies with very large sample sizes do show lower hospitalization rates with higher dialysis doses [87,88].

As indicated earlier, the use of nPNA or nPCR to estimate dietary protein intake requires that the patient is in neutral or near-neutral nitrogen balance. If a patient is in a net catabolic state, for example, a person with an inflammatory illness, the nPNA will usually overestimate dietary protein intake as these patients have an increased net generation of urea which will

**FIGURE 31.3** Exploring the association between nPNA and Kt/V<sub>sp</sub> in 122 MHD patients with a Kt/V<sub>sp</sub> value >1.20. No significant correlation existed between these two urea kinetic indices despite their known mathematical association ( $r = 0.09$ ,  $P > .20$ ). However, By dividing the patients into two distinct subgroups based on a Kt/V<sub>sp</sub> cutoff of 1.50, there was a strong, significant correlation between Kt/V and nPNA for the lower Kt/V<sub>sp</sub> values <1.50 ( $r = 0.54$ ,  $P < .001$ ), whereas there was essentially no correlation at higher Kt/V<sub>sp</sub> values ( $r = 0.03$ ,  $P > .20$ ). MHD, Maintenance hemodialysis; nPCR, normalized protein catabolic rate; nPNA, normalized protein nitrogen appearance. Source: Reprinted with permission from Kalantar-Zadeh K, Supasyndh O, Lehn RS, McAllister CJ, Kopple JD. Normalized protein nitrogen appearance is correlated with hospitalization and mortality in hemodialysis patients with Kt/V greater than 1.20. *J Ren Nutr* 2003;13(1):15–25.

increase nPNA (nPCR). On the other hand, nPNA may underestimate protein intake in patients with large protein losses (e.g., patients with the nephrotic syndrome or CPD patients with peritonitis) or in anabolic patients; for example, women in the last trimester of pregnancy, patients recovering from acute infection, and children with rapid growth.

PNA may change rather quickly after a shift in dietary protein intake or in the patient's catabolic state, and under these conditions, PNA may not reflect the patient's usual protein intake. Since body weight is in the denominator of the units for nPNA or nPCR (g/kg/day), the nPNA (nPCR) may be misleading in patients who are obese, have PEW, or are elderly and debilitated [89]. To accurately assess protein intake, it, therefore, has been proposed that nPCR (nPNA) should be normalized, preferably to some parameter related to the body weight of a normal person of the same height, age, and sex as the patient.

#### **Utility of the predialysis serum urea nitrogen level to estimate protein intake**

The SUN concentration at the beginning of a HD session (predialysis) can often be used to provide a rough estimate of the adequacy of an MHD patient's protein intake. The predialysis SUN reflects the balance between the removal of urea (by dialysis or RRF) and net urea generation from protein catabolism. In a

clinically stable person who is in protein balance, urea generation is largely determined by protein intake. There is a relatively small amount of urea recycling that occurs in the gastrointestinal tract, and unless the patient has a substantial acid load, the amount of amino nitrogen from degraded protein that is converted into ammonium by the kidney is small. Therefore when using the predialysis SUN to estimate protein intake, these latter two processes can largely be ignored, especially in advanced kidney failure where renal ammonium production is limited or absent. Thus an MHD patient with minimal RRF who is well dialyzed and has a sufficient protein intake (e.g., about 1.2-g protein/kg/day) should have a predialysis SUN of roughly around 90–100 mg/dL. A predialysis SUN of about 60 mg/dL or lower in a normally dialyzed patient with little or no RRF will indicate an inadequate protein intake, whereas a predialysis SUN of 100 mg/dL in a patient who is poorly dialyzed may also be consistent with a low-protein intake. On the other hand, a patient with substantial RRF (e.g., with a urine output of 300 mL/day or greater) can have a lower predialysis SUN with an adequate protein intake. Thus evaluating a combination of the predialysis SUN and the patient's clinical/catabolic status, adequacy of dialysis treatments and level of RRF may enable the physician to make a rough guess as to the adequacy of the patient's daily protein intake.

### **Acidemia and protein wasting**

Experimental evidence indicates that acidemia enhances protein catabolism [15,90–97]. In rats, acidemia increases the activity of branched-chain ketoacid dehydrogenase which is an enzyme involved in the catabolism of branched-chain amino acids [90]. Bergstrom et al. reported that there is a linear correlation between predialysis plasma bicarbonate levels and muscle-free valine in MHD patients [96]. This suggests that acidemia can enhance the degradation of at least some amino acids. Acidemia can increase protein catabolism and induce negative nitrogen balance [92]. This proteolysis induced by acidemia in skeletal muscle is due to enhanced activity of the ATP-dependent ubiquitin proteasome pathway [93–95]. Interestingly, even normal individuals who develop metabolic acidemia by ingesting ammonium chloride for several days reduce synthesis of albumin and develop negative nitrogen balance [98].

Acidemia in MHD patients may be common as evidenced by the frequent finding of low predialysis serum bicarbonate levels [10–12,99]. It is important to note that low serum bicarbonate is not definitive proof that acidemia exists. Direct pH measurements are a more accurate way to conclusively demonstrate acidemia. Published literature strongly suggests that acidemia is harmful, and, therefore, it is strongly recommended that bicarbonate supplements be given to maintain serum bicarbonate of 24–26 mEq/L (Clinical Practice Guideline 6.1.3) throughout the interdialytic interval unless it is determined that the low serum bicarbonate level is associated with normal arterial blood pH in a given patient [14]. Our experience indicates that the MHD patients most likely to develop acidemia during the interdialytic interval are those with substantial RRF, presumably because these individuals may have substantial urinary bicarbonate losses.

### **Goals of nutritional management in maintenance hemodialysis patients**

There are four goals for dietary therapy or nutritional intervention: (1) to achieve and maintain good nutritional and metabolic status, (2) to prevent or ameliorate uremic toxicity, (3) to prevent or treat hyperparathyroidism and renal osteodystrophy, and (4) to prevent or retard the development of cardiovascular disease. It is a challenge for many MHD patients to adhere to a special diet with its multiple restrictions. MHD patients often eat too little rather than too much. Due to these challenges, it is important to educate

patients on the principles of dietary therapy, including the rational, goals implementation of such therapy. Nutritional training also includes educating patients to read food labels, so they can ascertain the nutrient content of foods, and to assemble foods into meal patterns that are consistent with their dietary prescription. Even patients who have no interest in dietary management may benefit from nutritional training for several reasons. First, patients may decide to follow dietary therapy after they receive the education. Second, even if they adhere poorly to the prescribed diet, it may still provide some health benefits. Third, nutrition education may help motivate patients to not deviate further from a healthy nutrient intake. Nutritional training may be especially helpful if the patient's age and emotional or physical stresses are contributing to poor dietary compliance.

### **Dietary nutrient requirements**

#### **Dietary protein requirements**

There are no prospective randomized clinical trials examining the morbidity and mortality of MHD patients assigned to different levels of dietary protein intake as the independent variable (see Table 31.3). Several prospective studies compared the effects of dietary protein intake on the nutritional status of MHD patients. Most of these trials were conducted in hospital research wards with relatively small numbers of patients [100–102]. The studies that addressed protein requirements in HD patients were usually carried out several years ago and used dialyzers with lower solute clearances than those that are currently in use [101,102]. Other studies conducted retrospective analyses of larger numbers of patients that examined the relationship between dietary protein intake, assessed from nPNA, and morbidity and mortality [36,84,103,104].

The KDOQI guidelines on nutrition in chronic renal failure recommend a dietary protein intake of 1.0–1.2 g/kg body weight/day in stable MHD patients [14]. At least 50% of this protein intake should be of high biological value that ensures adequate intake of essential amino acids. These recommendations are based on the level of protein intake that for the great majority of clinically stable MHD patients (about 97%) should maintain neutral or positive nitrogen balance and lead to maintenance or improvement of nutritional or protein markers such as serum albumin. This is the same reasoning that has led to the development of the Recommended Daily Allowances for normal people by the National Academy of Medicine. It follows from this reasoning that if 1.2-g protein/kg/day will

TABLE 31.3 (Continued)

<sup>a</sup>According to KDOQI guidelines.<sup>b</sup>Refers to percent of total energy intake (diet plus dialysate).<sup>c</sup>Although atherosclerotic vascular disease constitutes a common and serious problem for MHD patients, these recommendations regarding dietary fat and carbohydrate are often difficult to adhere to. Moreover, there is no prospective interventional study that has examined whether these modifications of dietary fat and carbohydrate reduce morbidity or increase survival in CKD or MHD patients, although, reasonably, these modifications would seem to be beneficial. They are strongly recommended only if patients adhere closely to more critical aspects of the diet (e.g., sodium, water, potassium, phosphorus, protein, and energy intakes) and have expressed a particular interest in these modifications or have a specific disorder that may respond to their medications.<sup>d</sup>Refers to percent of total energy intake; if triglyceride levels are very high, the percentage of fat in the diet may be increased to about 35% of total calories; otherwise, 25%–30% of total calories is preferable. Intake of fatty acids should be kept low because they raise LDL cholesterol (see text).<sup>e</sup>Should be primarily complex carbohydrates.<sup>f</sup>Less critical to adhere to for the typical MHD patient.<sup>g</sup>Phosphate binders (aluminum carbonate or hydroxide, or calcium carbonate, or acetate) often are needed to maintain normal serum phosphorus levels.<sup>h</sup>These calcium intakes are commonly ingested because of the use of calcium binders of phosphate. Excess calcium intake must be avoided (see text).<sup>i</sup>Iron requirements vary according to the dose of administered erythropoietin.<sup>j</sup>Folic acid 1 mg/day should be routine, but up to 10 mg/day may be given to reduce elevated plasma homocysteine levels.<sup>k</sup>Vitamin E, 300 or 800 IU/day, may be given to reduce oxidative stress and prevent cardiovascular disease, but the value of these supplements is controversial (see text and Chapter 20: Nutritional Management of Sodium, Chloride and Water in Kidney Disease and Kidney Failure).<sup>l</sup>Vitamin K supplements may be needed for patients who are not eating and who receive antibiotics.

maintain protein balance for about 97% of clinically stable MHD patients, many such patients will maintain protein balance with a lower protein intake. The problem is that when prescribing the diet, it usually is not possible to know which MHD patients can maintain protein balance with lower protein intakes. Clearly more research is needed to address the protein needs of MHD patients. The following is a review of the research that has been published so far.

Kopple et al. reported results of nitrogen balance studies conducted on three MHD patients admitted to a metabolic unit [102]. These patients were receiving MHD for 11 hours twice weekly using a Kiil dialyzer. For about 3 weeks each, two separate isocaloric diets were given to these patients that provided 0.75-g protein or 1.25 g of primarily high biological value protein/kg/day. Nitrogen balance was negative or neutral with 0.75-g protein/kg/day diet (adjusted to unmeasured nitrogen losses) and strongly positive with 1.25-g protein/kg/day. Kopple et al. then carried out a study on 23 outpatient MHD patients assigned to receive either diet while they underwent with HD twice weekly for 10–12 hours with Kiil dialyzers. The estimated protein intake was about 0.8- to 0.9-g protein/kg/day in patients assigned to the low-protein diet and about 1.1- to 1.2-g protein/kg/day in those

assigned the high-protein diet. Those patients who received the low-protein diet had only a small improvement in their serum albumin and body weight. The high-protein group had a statistically significant improvement in serum albumin and body weight. Borah et al. studied five MHD patients given either 0.50- or 1.44-g protein/kg/day under metabolic balance conditions [18]. This diet was fed for only 7 days. The investigators concluded that high-protein diets resulted in neutral or positive nitrogen balance and low-protein diets caused negative nitrogen balance.

Ginn and coworkers performed nitrogen balance studies on four MHD patients undergoing MHD twice weekly [101]. Two of these four MHD patients were fed 18-g protein/day and were in severe negative nitrogen balance. The other two patients were fed higher protein diets. Their nitrogen balance was positive when they ingested 0.8 g/kg/day of primarily high biological value protein. Interestingly, nitrogen balance was sometimes negative with the higher protein diets when the protein was of low biological value. The positive nitrogen balance observed in MHD patients who received low-protein diets (i.e., 0.8-g protein/kg/day) may have been because these patients were severely malnourished, were receiving only twice-weekly dialysis, and this diet might have provided more protein than the patients had previously been eating. Shinaberger and Ginn reported that 10 MHD patients who ingested 0.75 g/kg/day showed improvement in nutritional status [105]. Most of these

patients were malnourished and had probably been eating poorly before the study. Since these patients received only twice-weekly dialysis, this may have limited both the amino acid, peptide, and protein losses during HD and the inflammatory, catabolic effects of HD (see earlier). These factors may explain the anabolic response with the low-protein diet the patients ingested. Also, the protein diet actually consumed by the patients probably exceeded 0.75 g/kg/day.

Slomowitz and coworkers reported metabolic studies conducted in six MHD patients [106]. The patients lived in a clinical research ward for 63–65 days and received HD three times weekly using Cuprophane or cellulose acetate dialyzers. Although this study was conducted to assess dietary energy needs, it also gave information on the protein needs of MHD patients. These patients were fed a constant protein diet throughout the study that provided  $1.13 \pm 0.02$  SEM g protein/day. Patients were fed three different energy intakes (25, 35, and 45 kcal/kg/day) in random order for 21–23 days each. Of the six patients the number that were in neutral or positive nitrogen balance with the 25, 35, and 45 kcal/kg/day intakes were one (possibly), four, and six individuals, respectively. Since the usual energy intake of clinically stable MHD patients is  $<30$  kcal/kg/day [107], these results suggest that for many of the MHD patients who ingest about 25 or even 35 kcal/kg/day, a dietary protein intake of 1.1 g/kg/day may not be sufficient to maintain protein balance. The nitrogen balance data with energy intake of 35 kcal/kg/day with protein intake of  $1.1 \pm 0.02$  SEM g/kg/day are shown in Table 31.4. These

balance studies suggest that some clinically stable MHD patients will not maintain protein balance with dietary protein intake of 1.1 g/kg/day and energy intakes providing 25 or 35 kcal/kg/day.

The KDOQI recommendations suggest that in patients who are metabolically stable, a dietary protein intake of 1.0–1.2 g/kg ideal body weight/day maintains stable nutritional status [14]. The current guidelines may be considered safe and justified until more data are available. The methods for calculating ideal body weight or even the use of this term are not conclusively validated in MHD patients.

### Retrospective and observational studies concerning dietary protein requirements

Data from retrospective and observational studies support the previous recommendation of 1.0- to 1.2-g protein/kg/day for MHD patients. Data from the National Cooperative Dialysis Study suggest that a dietary protein intake <0.8 g/kg/day (estimated by nPNA) is associated with increased morbidity [108]. These patients were randomized to a specific midweek predialysis SUN, and, therefore, the patients received a range of dialysis times and doses of dialysis. Therefore it is difficult to arrive at a firm conclusion that the morbidity was due to lower nutritional intake per se and not due to decreased dialysis dose. It should also be emphasized that due to the unmeasured nitrogen losses through respiration, skin, etc., in clinically stable people, the nPNA (nPCR) underestimates the dietary protein intake unless an adjustment factor is added [109].

Acchiardo et al., in a retrospective study, examined the relationship between dietary protein intake determined by nPCR and mortality, frequency of hospitalizations, and number of hospital days in 98 nondiabetic MHD patients followed for a 12-month period [103]. Based on their nPNA, patients were divided into four groups (nPNA of 0.63, 0.93, 1.02, and 1.2 g/kg/day). The frequency of hospitalization and mortality were inversely correlated with dietary protein intake. With an nPNA of 0.63 g/kg/day, the hospitalization rate and mortality was particularly likely to be elevated. It is not known whether an nPNA higher than 1.2 g/kg/day would be associated with a further reduce morbidity and mortality. Again, it should be recognized that the nPNA (nPCR) underestimates protein intake in clinically stable individuals unless a mathematical adjustment is made [109]. These data should be qualified because patients ingesting lower amounts of protein were probably more likely to be acutely or chronically ill, and this may have increased their risk for morbid events and mortality.

Although some investigators report that some MHD patients are in nitrogen balance at protein intake of 0.7 g/kg/day, these data, if typical for these patients, indicate that they are outliers [102,110]. Our analysis of the dietary protein data is in agreement with the KDOQI guidelines that a protein intake of 1.0–1.2 g/kg ideal body weight/day is much more likely to maintain healthy body protein mass and nutritional status in clinically stable MHD patients [14]. However, as indicated in the foregoing discussion, some stable MHD patients do not seem to maintain protein balance with an intake of 1.0 or 1.1 g/kg/day. Hence, in the absence of a specific contraindication (e.g., liver failure), it may be preferable to encourage MHD patients to ingest closer to 1.2-g protein/kg/day. If a patient is ingesting a lower protein intake and shows no evidence of PEW, it may be reasonable to not try to increase his/her dietary protein. On the other hand, a clinically stable MHD patient who shows signs of developing PEW or who has PEW and who is ingesting 1.1-g protein/kg/day or less, may be encouraged to increase his protein intake to 1.2- or 1.3-g protein/kg/day [111]. A retrospective study that demonstrated a positive association between dietary protein intake and survival in MHD patients supports the potential benefit of even a slightly higher protein intake in these individuals [36].

### Dietary energy requirements

Epidemiological studies in MHD patients suggest that suboptimal energy intake is even more common than inadequate protein intake [104,107,112–116]. Even in the HEMO study, where energy intake was closely monitored by renal dieticians, the average energy intake was  $22.8 \pm 8.8$  SD kcal/kg adjusted body weight/day [107,117,118]. The low energy intakes of MHD patients do not reflect a decrease in energy requirements [119,120]. Studies indicate that basal metabolic energy expenditure in MHD patients during resting conditions is normal [121] or possibly slightly increased. Resting basal energy expenditure was compared in one study between 12 normal subjects and 16 MHD patients [119]. In the normal subjects, it was  $0.94 \pm 0.24$  and in the MHD patients was  $0.97 \pm 0.1$  kcal/min/1.73 m<sup>2</sup> [119].

Schneeweiss et al. performed indirect calorimetry on 24 normal adults and 86 subjects with CKD in different stages; 25 of the 86 CKD patients were receiving MHD [122]. The resting energy expenditure of the MHD patients was  $1.03 \pm 0.04$  SEM kcal/min/1.73 m<sup>2</sup> in MHD patients and was  $0.96 \pm 0.02$  in the control subjects. This difference in energy expenditure between the MHD patients and normal adults was not

significantly different. Neyra et al. measured resting energy expenditure by indirect calorimetry using a metabolic chamber (whole room indirect calorimeter) in 15 nondialyzed patients with advanced CKD, 15 MHD patients, and 10 CPD patients who had undergone 12 hours of fasting [123]. Energy expenditure was measured in the MHD patients on days when they were not receiving dialysis. Resting energy expenditure, adjusted for fat-free mass, was similar in the MHD and CPD patients and was significantly greater in each of these groups than in the nondialyzed advanced CKD patients ( $P < .05$ ). Resting energy expenditure in the patient groups was about 10%–20% higher than the predicted values for normal people. However, the normal values for energy expenditure were calculated and not measured.

In contrast to these findings, Monteon et al. found that resting energy expenditure, measured by indirect calorimetry, was similar in nondialyzed advanced CKD patients, MHD patients, and normal control individuals [119]. Energy expenditure in these three groups also did not differ from each other when they were sitting quietly, undergoing a specified amount of physical exertion, or after ingesting the same, defined meal [119]. Energy expenditure was reported to be increased in MHD patients during an HD session [123]. These patients were fed before their HD, and their increased energy expenditure may have been due to the specific dynamic action of foods. Energy expenditure may be increased in MHD patients who have increased serum CRP levels.

Slomowitz et al. showed in the previously described study that in six clinically stable MHD patients who were fed, in a research ward, a constant protein diet that provided, in random order, 25, 35, or 45 kcal/kg/day, both changes in their body weight and their nitrogen balances correlated directly with the dietary energy intake [106]. The average nitrogen balance was neutral when patients ingested 35 kcal/kg/day, although not every patient was in neutral or positive nitrogen balance.

The usual energy intake of MHD patients, as reported in many studies, seems to be inadequate in comparison to their needs, since their skinfold thicknesses, and, hence body fat, are low. The exception to this is that patients who begin MHD therapy obese tend to remain obese during the course of their treatment. There is also an altered risk factor pattern between obesity and survival in MHD patients. MHD patients who have larger body mass tend to survive longer [70,124–126].

The KDOQI guidelines recommend that daily energy intake should be 35 kcal/kg/day for MHD patients who are <60 years of age and 30–35 kcal/kg/day for those who are 60 years or older [14]. This recommendation is

based on the following findings: (1) the energy expenditure of MHD patients is similar or, at most, slightly increased in comparison to that of normal healthy individuals who are resting or performing mild physical activity. (2) Metabolic balance studies of MHD patients indicate that a total daily energy intake of about 35 kcal/kg/day induces neutral nitrogen balance in most MHD patients and is adequate to maintain serum albumin and anthropometric indices. (3) Individuals who are 60 years or older tend to be more sedentary and, hence, expend less energy. Therefore a slightly lower total energy intake of 30–35 kcal/kg/day should be sufficient. These recommendations are similar to the recommended dietary allowances for sedentary healthy adults by the Food and Nutrition Board of the National Research Council (Food and Nutrition Board; Dietary Reference Intakes: National Academy Press: Washington DC, 2001).

## Lipids and hemodialysis

Management of lipid disorders has the theoretical potential to change cardiovascular morbidity and mortality in MHD patients. Cardiovascular mortality accounts for half of the mortality in chronic dialysis patients with about one-quarter of total deaths attributable to sudden cardiac death [127–130]. Dyslipidemia is more prevalent in ESRD patients than in the general population [131,132].

In the general population, elevated serum total cholesterol and low-density lipoprotein (LDL) cholesterol levels are associated with increased mortality. In a striking example of the altered risk factor patterns that occur in chronic dialysis patients, the low serum total cholesterol levels (below 200–250 mg/dL) and decreased (LDL) levels that may occur in MHD patients are associated with increased mortality [133,134]. This altered association has been attributed to inflammation which can both lower serum LDL and total cholesterol and increase mortality.

Hypertriglyceridemia and low serum high-density lipoprotein (HDL) concentrations often occur in MHD patients [135,136]. Very LDL is usually increased, but LDL and total cholesterol levels are normal or reduced compared to the general population [137–139]. Increased serum apolipoprotein B containing triglyceride-rich lipoprotein particles, such as lipoprotein Bc, and elevated lipoprotein(a) [LP(a)], are also independently associated with increased risk of myocardial infarction and death in patients with renal failure [140–143]. Reduced clearance of serum LP(a) is a cause of elevated serum levels in advanced CKD and ESRD patients. LP(a) can inhibit fibrinolysis, leading to thrombosis and atherosclerosis. Postprandial clearance of chylomicron remnants is

reported to be defective in MHD patients [144,145]. Type 4 hyperlipidemia is frequently seen in ESRD patients [140–144,146].

All fractions of serum HDL cholesterol are often decreased, possibly due to reduced lecithin–cholesterol acyltransferase activity. Serum HDL-3 is not affected. Serum HDL-3 is not one of the major risk factors for reduced adverse cardiovascular events. An elevated serum HDL-2 on the other hand has a strong association with lower cardiovascular morbidity and mortality, and HDL-2 is significantly reduced in ESRD patients. The antiatherogenic HDL-associated Apo A1 and Apo A2 are also reduced in ESRD patients. Lipoprotein lipase activities in serum and liver are decreased. Serum levels of oxidized lipids and thiobarbituric acid reactive substances are elevated in CKD and MHD patients. Schletter et al. report that lipid oxidation is not increased in MHD patients [147], although other researchers have hypothesized that it may be increased.

MHD patients with hypertriglyceridemia should be evaluated for systemic causes of this disorder, such as hypothyroidism and DM. Hypertriglyceridemia is more common than hypercholesterolemia in MHD patients. When the serum triglyceride concentrations are 1.25–1.50 times the upper limit of normal values, dietary interventions may be used and are effective. Dietary therapy includes decreased intake of ethanol, purified sugars, and saturated fat. If after institution of these interventions, serum triglycerides are not reduced sufficiently (i.e., after a 10-hour fast serum triglycerides remain >500 mg/dL), medications can be considered. Medical therapy can be given concurrently with lipid-lowering diets [148–150]. Gemfibrozil and such fibric acid derivatives as clofibrate are effective medications to reduce serum triglyceride levels. According to the KDIGO guidelines, there is very little evidence that the use of fibrates in CKD patients is clinically beneficial, unless serum triglyceride levels are >1000 mg/dL [151]. Adverse effects of these medications include rhabdomyolysis, and a dose reduction should be made for MHD patients [152–155].

There is currently no consensus as to the optimal lipid composition of the diet for MHD patients. The National Cholesterol Education Program Expert Panel has recommended the Therapeutic Lifestyle Changes (TLC) diet for all individuals with serum LDL cholesterol of 100–125 mg/dL or greater or serum triglycerides higher than 180 mg/dL [156]. Table 31.5 shows the nutrient composition of the TLC diet. Its key features are (1) reduced intake of saturated fats (to <7% of total calories) and cholesterol (to <200 mg/day). (2) Sources of total calories in the diet should include up to 10% from polyunsaturated fats, up to 20% from

TABLE 31.5 Nutrient composition of the therapeutic lifestyle changes diet.

Nutrient	Recommended intake
Saturated fat <sup>a</sup>	<7% of total calories
Polyunsaturated fat	Up to 10% of total calories
Monounsaturated fat	Up to 20% of total calories
Total fat	25%–35% of total calories
Carbohydrate <sup>b, c</sup>	50%–60% of total calories
Fiber	20–30 g/d
Protein <sup>c</sup>	Approximately 15% of total calories
Cholesterol	<200 mg/d
Total calories <sup>d</sup>	Balance energy intake and expenditure to maintain desirable body weight/prevent weight gain

<sup>a</sup>Trans fatty acids are another LDL-raising fat that should be kept at a low intake.

<sup>b</sup>Carbohydrates should be derived predominantly from foods rich in complex carbohydrates, including grains, especially whole grains, fruits, and vegetables.

<sup>c</sup>Dietary content of protein and, hence carbohydrate, should be modified according to the specific needs of the MHD (i.e., 1.20-g protein/kg/day) (see text).

<sup>d</sup>Daily energy expenditure should include at least moderate physical activity (contributing approximately 200 kcal/day).

LDL, Low-density lipoprotein; MHD, maintenance hemodialysis.

From Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults. Executive summary of the third report of the National Cholesterol Education Program (NCEP) expert panel on detection, evaluation and treatment of high blood cholesterol in adults: adult treatment panel III. JAMA 2001;285:2486–97.

monounsaturated fats, 25%–35% from all fat sources, and the rest from protein and carbohydrates. Dietary protein in the TLC diet should provide 1.20-g protein/kg/day, and dietary carbohydrate should be modified accordingly to maintain the desirable energy intake. (3) Consider therapeutic options for lowering serum LDL by ingesting plant sterols (2 g/day). (4) Attainment and maintenance of desirable body weight and expend at least about 200 kcal/day in physical activity.

KDIGO and KDOQI clinical practice guidelines do not recommend starting a statin medication (3-hydroxy-3-methyl-glutaryl (HMG) coenzyme A inhibitor) or the combination of a statin with ezetimibe, an intestinal cholesterol absorption inhibitor, in MHD patients because there is no clear evidence that decreasing serum LDL cholesterol reduces morbidity or all-cause mortality in these individuals. One hypothesis to explain this lack of benefit in all-cause mortality is that sudden cardiac death in MHD patients is not related to obstructive atherosclerotic lesions that can be modified by statins; the sudden death in these patients might be related to heart failure and/or arrhythmias due to eccentric and or

concentric cardiac hypertrophy [157]. Another possibility is that the statin therapy was studied for periods of about 5 years in these clinical trials, whereas the process of atherosclerosis had begun many years earlier; therefore the statin treatment might have been inaugurated too late to be very effective.

It is reasonable to recommend that if a patient is already taking statins before the initiation of MHD, the patients should continue taking statins. This latter recommendation is mostly based on the SHARP trial that examined 2141 patients with CKD that progressed to requiring dialysis [158]. The patients in this study who were taking simvastatin, 20 mg/day, and ezetimibe, 10 mg/day, had a significant reduction in major cardiovascular events.

### ***Long-chain omega-3 polyunsaturated fatty acids***

The KDOQI guidelines recommend that MHD patients can be prescribed 1.3–4.0 g/day long-chain omega-3 polyunsaturated fatty acids (LC  $n-3$  PUFA) to reduce serum triglycerides, reduce serum LDL cholesterol, and increase serum HDL levels [14]. The KDOQI guidelines also suggest that LC  $n-3$  PUFA, including those derived from fish or flax seed and other oils, should not be routinely prescribed to lower risk of mortality or cardiovascular mortality [14]. We agree with this suggestion. These should be prescribed only to reduce elevated triglycerides, reduce LDL cholesterol, and increase serum HDL levels.

## **Sodium and water**

### ***Interdialytic weight gain and its relation to salt and water intake***

Management and monitoring of IDWG is critical to preventing and/or reducing the risk of volume related hypertension, left ventricular hypertrophy, congestive heart failure, and right heart failure [159,160]. Dietary counseling to avoid high salt and fluid intake is, therefore, critical to limit large IDWG in MHD patients. Fluid removal  $>13$  mL/kg/hour during HD in MHD patients has been linked to such adverse events as intradialytic hypotension and myocardial stunning [161–164]. It is, therefore, critical for patients to limit their salt and water intake for as long as they are receiving MHD to avoid cardiovascular complications.

Reduction or complete avoidance of antihypertensive medications can be achieved at least in some patients with diligent restriction of salt and water intake during the interdialytic period. Shaldon and Tomson have reported medication-free blood pressure control with aggressive salt and fluid restriction. The KDOQI guidelines recommend both salt and water

restriction, since restriction of only water intake will lead to increased serum osmolality which will stimulate thirst-related water intake [14]. MHD with longer than 4-hour HD sessions or conducted more frequently than thrice weekly are other effective ways to attain good blood pressure control, often with the need for only little or no antihypertensive medications.

Salt (sodium chloride) intake should be limited to no  $>5$  g/day (2 g/day of sodium). One study described the average daily salt intake in MHD patients in the United States to be between 7.9 and 14.1 g/day [165]. To reduce dietary salt intake, almost all people must make substantial changes from their old habits of food intake and cooking—for the people who prepare the food. These changes are emotionally wrenching for many people. To attain these goals, significant effort must be directed toward dietary counseling. Dietitians must be supported in this effort by the other members of the health-care team (i.e., doctors, nurses, social workers, technicians, and unit administrators).

Some medications are sources of sodium intake. Examples of this include combined analgesics in effervescent form. An example is cocodamol, a combination of codeine and paracetamol, used mostly in Europe. This preparation contains 19.1 mmol (438 mg) of sodium in each tablet. If a patient takes six to eight of these tablets, the excess sodium intake can cause increased thirst and, as a result, may result in approximately an 800-mL increase in water intake per day to maintain a normal plasma sodium concentration.

### ***Strategies used in selected studies to reduce salt and water intake***

Sevick et al. reported that nutritional counseling, social cognitive theory-based behavioral counseling for 16 weeks failed to reduced dietary salt intake and, as a result, did not reduce IDWG [166]. Telini et al. showed that restriction to 2-g sodium/day did not reduce IDWG [167]. Kayikcioglu et al. studied patients from two dialysis units, one dialysis unit was practicing an antihypertensive salt restriction–based strategy and the other dialysis unit practicing an antihypertensive drug-based strategy [168]. The patients who were in the salt restriction–based strategy did have significantly lower IDWG. In another study, nutritional counseling was conducted over 48 months and resulted in decreased salt and water intake, from  $13.3 \pm 2.7$  to  $11.8 \pm 2.4$ -g sodium chloride/day and  $2528 \pm 455$  to  $2332 \pm 410$  g water/day [169]. Another important reason to provide dietary counseling to MHD patients on water and mineral intake is to reduce the risk that the patient's intake may deviate even further from an optimal diet.

**FIGURE 31.4** Association of fluid gain between two consecutive hemodialysis treatment sessions and 2-year cardiovascular mortality in 34,107 MHD patients. MHD, Maintenance hemodialysis. Source: Adapted from Kalantar-Zadeh K, Regidor DL, Kovesdy CP, et al. Fluid retention is associated with cardiovascular mortality in patients undergoing long-term hemodialysis. *Circulation* 2009;119(5):671–9.

### Studies evaluating the relationship between interdialytic weight gain, hypertension, and mortality

The 2-year mortality was examined in 34,107 MHD patients in the United States [170]. The 3-month average IDWG was divided into eight categories of 0.5-kg increments: up to, greater than, or equal to 4.0-kg weight gain. Of these patients, 86% gained >1.5 kg between two dialysis sessions. Once multivariate adjustment was made for demographics and markers of the malnutrition–inflammation complex, higher weight gain increments (>0.5 kg) were associated with increased risk of all-cause and cardiovascular death (Fig. 31.4). These findings suggest that it is prudent to limit fluid gain between two subsequent HD sessions, as it is linked to higher risk of all-cause and cardiovascular death.

A number of smaller studies have shown that high IDWG contributes to hypertension, but some studies have not shown that relationship or found this relationship only in “volume-responsive” patients [171–173]. Hypertension in dialysis patients can be purely volume related, can be due to a combination of volume and hormone related (e.g., catecholamines, renin, angiotensin, and aldosterone), or can be purely hormone related. The association between the expansion in total body water or extracellular volume and hypertension is thought to be due to the associated increase in plasma volume and possibly vascular wall sodium.

In a large study of MHD patients, those with low IDWG were at higher risk of dying and also those with a very high IDWG had a modest increase in risk of death [174]. The patients with a low IDWG who had an increased mortality were probably patients who

had increased comorbidity with PEW and poor oral intake. PEW, by itself, is a powerful predictor of poor outcome in MHD patients (see earlier). Even though there are some studies, usually involving inadequate number of patients, which show no relationship between IDWG and hypertension or mortality, the preponderance of evidence strongly indicates that it is important to keep IDWG to as low as tolerated by sodium and water restriction.

The sodium concentration in hemodialysate is another factor that has been examined for its relationship to IDWG. The Dialysis Outcome and Practice Pattern (DOPPS) study reported a decline in IDWG in the last decades in the United States and Europe [175]. This was in part explained by reduction in sodium in the hemodialysate. Studies are currently examining clinical outcomes with different dialysate sodium concentrations. Many dialysis centers use a sodium concentration of around 135–138 in the dialysate. The benefit of a reduction in IDWG with a lower dialysate sodium concentration has to be balanced against the risks of such adverse effects as hypotension [176].

### Water intake

The majority of MHD patients are oliguric or anuric, and, therefore, water intake should be limited to 750–1500 mL/day, including the water consumed with food, unless the patient has urine output above the oliguric range. Too much water intake between dialysis treatments is one of the main reasons for excessive IDWG. Thirst, which is deranged, and xerostomia have been reported to lead to large IDWGs in dialysis patients [177].

## Potassium

Before and after MHD is initiated, patients should receive detailed counseling on avoiding high potassium-containing foods. They must be informed about foods which have high-potassium content. Severe hyperkalemia (serum potassium of 7.0 mmol/L or greater) can precipitate fatal cardiac arrhythmias. In MHD patients a diet providing no >70 mmol/day (roughly 2.8 g/day) should be prescribed [178]. This restricted diet is tolerated by most but not all MHD patients. Education regarding diets that are low in potassium (i.e.,  $\leq 70$  mEq/day) ideally should be conducted during the months and weeks leading up to inauguration of dialysis.

Epidemiological studies indicate that serum potassium >5.3 mEq/L is associated with increased mortality in MHD patients [179]. The dietary intake of potassium (estimated using the Block Food frequency Questionnaire) as a predictor of mortality was studied in 224 MHD patients [180]. Mortality was examined over a 5-year period, from 2001 to 2006. MHD patients with higher potassium intakes had greater dietary energy, phosphorous, and protein intake and had higher predialysis serum potassium and phosphorous [180]. Greater potassium intake was associated with significantly increased death risk in unadjusted models and after incremental adjustments for case-mix and such nutritional factors as the 3-month averaged predialysis serum creatinine, potassium, and phosphorous levels, Basic Metabolic Panel (BMP), nPNA, dietary energy, protein, and phosphorus intake, and also serum levels of inflammatory markers.

In the past, very low-potassium dialysate, containing 0–1.0 mmol K/L, was used in outpatient and incenter HD units, especially in the United States. However, there has been increasing awareness of the risks of sudden cardiac death associated with postdialysis hypokalemia. Due to this risk of postdialysis hypokalemia in MHD patients who were treated with very low-potassium dialysate, these dialysate solution has largely been abandoned in outpatient HD units. Karnik et al. reviewed records of 400 cardiac arrests over a 9-month period in a nationally representative cohort of 77,000 MHD patients dialyzed at outpatient HD units in North America [181]. They reported that cardiac arrests were nearly twice as likely to occur in patients who had been dialyzed with dialysate containing 0–1.0 mEq/L potassium on the day of the cardiac arrest (17.1% vs 8.8%). Since many large cohort studies have identified an increased risk of sudden cardiac death associated with very low-potassium dialysate (<2 mEq/L), most dialysis units, at least in the United States, avoid very low-potassium dialysate and employ longer hours (4 or more hours) per dialysis

session to control serum potassium, if necessary [182]. It is also important to recognize the potential hazards of higher potassium ( $\geq 3$  mEq K/L) dialysate concentrations. The association of mortality rates with dialysate potassium and predialysis serum potassium concentrations was examined in a cohort of over 81,000 MHD patients [179]. The greatest mortality was observed in patients who underwent MHD with dialysate potassium concentrations above 3 mEq/L or who had predialysis serum potassium levels of 5 mEq/L or higher. A study of Canadian MHD patients showed increased death rates when the dialysate potassium was 3 mEq/L or greater [183]. A similar finding of increased mortality with dialysate potassium  $\geq 3$  mEq/L was reported in the DOPPS cohort [184]. The safety of using graded dialysate potassium concentrations has not been examined in large-scale studies. It would seem prudent to use very low-potassium dialysate (<2 mEq/L) only during the first hour of HD in patients with hyperkalemia. This strategy needs to be examined in clinical trials.

A standard HD session removes 70–100 mEq of potassium (210–300 mEq/week) for patients who receive HD three times weekly. HD removes potassium from the extracellular compartment, which has only 2% of the total body potassium, whereas 98% of body potassium is in the intracellular compartment. The majority of potassium removed (almost 85%) during HD occurs through diffusion and is dependent on the dialysate–blood potassium gradient. Substantial losses of potassium occur through fecal excretion, especially in people with chronic kidney failure in whom fecal potassium excretion, roughly 17 mEq/day, is greater than normal [185]. It has been suggested that it is important to avoid constipation in chronic dialysis patients to prevent potassium accumulation and hyperkalemia.

### ***New medications to lower serum potassium levels in maintenance hemodialysis patients***

In patients who continue to have predialysis serum potassium >5.3 mEq/L despite strict dietary counseling and other dietary interventions, medications to lower serum potassium should be considered. First, recirculation of blood at the vascular access should be checked as a cause of persistent hyperkalemia before medications to lower potassium are prescribed.

Sodium zirconium cyclosilicate and patiromer are effective cation exchangers that exchange such cations as sodium and calcium for potassium in the gastrointestinal tract. When dietary counseling and dietary restriction are not effective, and MHD patients continue to develop hyperkalemia, these newer medications can be used. The binding affinity of these newer medications for potassium is high, and they are much more effective

than sodium polystyrene. There is a risk of increased sodium absorption with zirconium. These medications should be avoided in patients who are postoperative from abdominal surgery, who take opiates, or who have poor gastrointestinal mobility from other causes. Limiting dietary intake of potassium remains the cornerstone of preventing and treating hyperkalemia.

## Magnesium

A typical 24-hour diet contains approximately 360-mg magnesium of which there is net absorption of about 50% in the gastrointestinal tract. Normal kidneys excrete roughly 100-mg magnesium/day [186]. The normal plasma concentration of magnesium is 0.65–1.0 mmol/L (1.3–2.0 mEq/L or 1.6–2.4 mg/dL). Only 1% of total body magnesium is found in the extracellular compartment.

Hypomagnesemia can cause prolonged QT intervals and increase the risk of ventricular arrhythmias [187–189]. This risk is even more elevated if hypokalemia and hypomagnesemia are present together. Dialysis prescription for MHD patients, therefore, should be designed to avoid hypomagnesemia. Magnesium disorder occurs in dialysis patients more frequently is realized and, therefore, is not as commonly considered as it should be [190,191]. Mild hypermagnesemia is frequently present in MHD patients, but severe hypermagnesemia is rare. Hypermagnesemia, however, is more common if magnesium-containing antacids or laxatives, such as Maalox, Gelusil, milk of magnesia, or cascara sagrada, are consumed in large amounts or on a routine basis [186]. MHD patients are reported to have increased magnesium content in bone and soft tissues [192–194]. Patients with advanced CKD who are not on dialysis have a dietary magnesium requirement of about 2–4 mg/kg/day, which is about 200 mg/day [195]. MHD patients usually maintain normal or slightly elevated predialysis serum magnesium levels when their hemodialysate contains 1.0 mEq/L of magnesium.

Serum magnesium is approximately 25% protein bound and 5%–16% of serum magnesium is complexed with such anions as bicarbonate, phosphate, and citrate. Serum magnesium, therefore, is not freely cleared by the HD membrane [196]. The amount of magnesium cleared is dependent on the concentration of magnesium in the dialysate; therefore dialysate prescription is important. If the serum magnesium is in the normal range and the dialysate magnesium is 0.75 mmol/L, about 565 mg of magnesium will be cleared during a 4-hour standard HD session. If the serum magnesium is in the normal range and the dialysate concentration is 0.25 mmol/L, about 3100 mg of

magnesium will be cleared. Alhosaini et al. reported that hypomagnesemia occurs 33% of the time at hemodialysate magnesium concentrations of 0.25 mmol/L (0.5 mEq/L) but occurs only 5% of the time in patients with hemodialysate magnesium of 0.5 mmol/L (1.0 mEq/L) [196].

## Calcium

The Recommended Daily Allowance for calcium in normal nonpregnant, nonlactating adults is 1000–1200 mg/day. The daily calcium requirement is estimated to be 800–1000 mg/day in healthy adults as proposed by Institute of Medicine. In adults with CKD 3 and 4 who are not receiving active vitamin D analogs, daily calcium of 800–1000 mg/day is considered adequate to maintain calcium balance [14]. In advanced CKD and MHD patients, deficiency of various vitamin D compounds (e.g., 25-hydroxycholecalciferol and 1,25-dihydroxycholecalciferol) and resistance to the actions of vitamin D can increase the dietary calcium requirements. MHD patients are recommended to consume about 800–1000 mg of calcium/day. Phosphorus-rich foods are often rich in calcium, and restriction of high phosphate content foods will also reduce calcium intake. On the other the hand, it is not uncommon for MHD patients to take calcium-containing phosphate binders, and this can lead to calcium intakes of 1.0–1.5 g/day or greater. Daily calcium intake can exceed 3.0 g/day from a combination of calcium-containing phosphate binders and foods high in calcium content. A high calcium intake increases intestinal absorption of calcium, and this poses a risk for soft tissue calcium deposition. To control soft tissue calcification, including vascular calcification, the dialysate calcium is often prescribed at 1.25 or 1.5 mmol/L (5.0–6.0 mg/dL) in patients who take calcium-containing phosphate binders. Since much of serum calcium is protein bound or complexed to other compounds, in a patient with normal serum calcium concentrations, this level of ionized calcium in dialysate should lead to no calcium exchange or possibly a small transfer of dialysate calcium into the patient.

Goodman et al. were one of the first to show extensive coronary artery calcification in young adults with ESRD [197]. Several reports have raised concerns about the contribution of oral calcium intake to the development of coronary calcification and atherosclerotic plaques in MHD patients [198]. Calcium load and hyperphosphatemia accelerate vascular calcification [199–201]. A number of studies have shown that the risk of coronary artery calcification and vascular calcification is significantly reduced when noncalcium-containing phosphate binders, as compared to calcium-containing ones, are used [202,203].

Sevelamer hydrochloride is a popular intestinal phosphate binder that does not contain calcium. However, sevelamer hydrochloride may contribute to metabolic acidosis. In a randomized clinical trial of 129 incident MHD patients, calcium acetate was compared to sevelamer hydrochloride [204]. Coronary artery calcification was greater in the patients who used the calcium-containing phosphate binder [204].

These reports led to a consensus that calcium-containing phosphate binders should be avoided if possible. In the Dialysis Clinical Outcomes Revisited analysis, which compared calcium acetate to sevelamer hydrochloride, there was lower incidence of cardiovascular death and hospitalization in the calcium-binder group [205]. However, it is important to keep in mind that the sevelamer resin also binds and lowers serum cholesterol. In patients in whom calcium-containing phosphate binders are required, it is best to keep the calcium intake from foods <800 mg/day.

In large epidemiological studies of MHD patients, both high (>10.5 mg/dL) and low serum calcium levels (<8.0 mg/dL) are associated with an increased mortality risk [206]. Patients who receive both calcium salts and 1,25-dihydroxycholecalciferol (1,25-dihydroxyvitamin D) should be monitored for hypercalcemia. The risk of calciphylaxis, metastatic calcification, pruritus, and hypertension increases significantly in MHD patients when the serum calcium-phosphorous product exceeds 70. Therefore it is considered important to maintain the serum calcium-phosphorus product <60 [207,208].

### Phosphorus (target range, phosphate binders, organic vs inorganic phosphorus)

Although randomized controlled trials are necessary to precisely define the optimum target level for serum phosphorus in MHD patients, a target range for serum phosphorous of 3.5–5.5 mg/dL seems reasonable [209]. Serum phosphorous levels >5.5 are associated with increased mortality [209–212].

Dietary phosphorous restriction is the cornerstone of the management of hyperphosphatemia in chronic dialysis patients. It is noteworthy that there are no randomized prospective studies that show reduction of serum phosphorous with medications (e.g., phosphate binders) reduces mortality in chronic dialysis patients [213], although such studies would be difficult to conduct today. Observational studies do support improved survival with phosphate binders [214,215].

The 2015–16 NHANES indicates that in American adults aged 20 and older, the average daily phosphorus intake from foods is 1189 mg for women and

1596 mg for men [216]. This is most likely a substantial underestimate of the actual phosphorus intake, because it does not include much of the daily phosphorus intake from food additives. Roughly 60% of ingested phosphorus is absorbed via the gastrointestinal tract. Organic plant-based phosphorus is absorbed to a somewhat lesser extent than inorganic phosphorus [217].

Depending on the predialysis serum phosphorus concentration and the dialysis dose delivered, approximately 250 mg of phosphorus is removed with each HD session [218]. Therefore HD alone is not a very efficient method to remove the increased phosphorus burden and elevated serum phosphorus commonly seen in MHD patients, and dietary phosphorus restriction is the key to serum phosphorus control. It is recommended that MHD patients consume about 10–17 mg/kg/day of phosphorous [14,195,219]. The phosphorous content of the diet is directly related to the quantity of protein, dairy products, and certain cola drinks in the diet [195,219]. Hypophosphatemia in MHD patients, which often indicates a poor appetite and a low-protein intake, as well as hyperphosphatemia, is associated with poor outcomes in MHD patients [220].

Very low-phosphorus diets (e.g., <800 mg/day) are often less palatable, and, therefore, patients may find it very difficult to follow severely restricted phosphorus diets. Moreover, since the protein and phosphorus content of the diet are usually correlated, it is usually difficult to substantially reduce phosphorus intake without decreasing the protein intake. Indeed, a typical method that dietary counselors may use to decrease dietary phosphorus intake is to reduce the protein intake as well. In a large epidemiological study, Shinaberger et al. found that MHD patients had a rise in protein intake (measured by the nPNA over 6 months) and a low predialysis serum phosphorous level had greater survival than the MHD patients who displayed a rise in both protein intake and serum phosphorus levels [84]. The worst survival was in those MHD patients who had a low-protein intake and low serum phosphorus levels [84]. These data underscore the importance of not inducing protein wasting during the process of implementing dietary phosphorus restriction.

Because severe dietary phosphorus restriction is usually impractical and the amount of phosphorus removed with usual HD, ≤4 hours thrice weekly, is insufficient to maintain normal predialysis serum phosphorus, phosphate binders that bind phosphorus in the intestinal tract are usually required. Phosphate binders are used to augment dietary phosphorus restriction to attain desirable serum phosphorus levels in MHD patients. The binders usually do not bind

sufficient amounts of phosphorus to replace the need for low-phosphorus diets.

Aluminum-containing binders (aluminum hydroxide, aluminum carbonate) were among the earliest phosphate binders. These binders led to the serious side effects of low turnover bone disease, refractory anemia, and dementia. Calcium-containing phosphate binders were a significant improvement over aluminum-containing binders. Calcium carbonate contains 40% calcium by weight. Calcium acetate contains 25% calcium, and calcium citrate, 21% calcium. The major drawback of calcium-based binders is that they increase intestinal calcium absorption that is associated with enhanced calcium accumulation in soft tissue, including vascular calcification. Calcium-free phosphate binders, such as sevelamer hydrochloride, offered the advantage that it is polymeric amine and does not provide a calcium load; in addition, it binds lipids which results in lowering of serum cholesterol.

Aluminum-containing phosphate binders have superior phosphate-binding potency compared to most of the calcium-containing and calcium-free phosphate binders and, therefore, can be combined for short periods of time with other noncalcium binders for patients with very high serum phosphorus levels (e.g., serum phosphorus  $>8.0$  mg/dL) or those with a serum calcium–phosphorus product of about 70 or greater. Calcium citrate should not be combined with aluminum-based phosphate binders because citrate increases intestinal aluminum absorption. Calcium acetate is a more effective phosphate binder on a weight-to-weight comparison, presumably because it is more effective at a broader range of pH and may be associated with less hypercalcemia. Some studies, however, indicate that the incidence of hypercalcemia is similar with both calcium acetate and calcium carbonate, and gastrointestinal symptoms such as nausea, bloating, and constipation are more common with calcium acetate [221,222]. Large doses of calcium-based binders are associated with higher risk of coronary artery calcification and have also been implicated as a cause of adynamic bone disease [197,223,224].

Preliminary studies indicate that sevelamer hydrochloride is associated with a lower incidence of both hypercalcemia and coronary artery calcification, possibly because of the cholesterol-binding properties of sevelamer [204]. The hydrochloride in sevelamer hydrochloride may lead to hyperchloremic acidosis, especially at higher doses (e.g., 4–7 g three times daily) [225]. Sevelamer carbonate, which does not contain the hydrochloride, does not cause metabolic acidosis [225].

Lanthanum carbonate and trivalent iron-containing compounds are other noncalcium-containing phosphate binders that are approximately as potent as the

calcium-containing binders [226,227]. Unlike sevelamer hydrochloride, lanthanum does not cause metabolic acidosis. Individuals who take lanthanum carbonate develop small increases in tissue lanthanum levels; this has not resulted in any recognizable adverse side effects. Kendrick et al. reported results of 530 MHD patients who transferred from noniron-based phosphate binders to sucroferric oxyhydroxide. This resulted in a twofold higher likelihood of controlling serum phosphate in the target range and also was associated with a reduction in the daily pill burden.

There are currently no randomized controlled trials that conclusively establish the ideal predialysis or postdialysis serum phosphorus levels for MHD patients. Current recommendations, therefore, are based on observational studies and virtually exclusively focus on the predialysis serum phosphorus. Kalantar-Zadeh et al. examined the relationship between predialysis serum phosphorus levels and mortality in 58,000 MHD patients [228]. The risk of death was significantly higher with predialysis serum phosphorus levels equal to or greater than 6.0 mg/dL as compared to serum phosphorus levels of 5.0–5.99 mg/dL. The DOPPS data compared the hazard ratios for cardiovascular death in MHD patients with serum phosphorus levels of 5.0–5.99, 6.00–6.99, and  $\geq 7.0$  mg/dL. The hazard ratios for cardiovascular mortality were 1.25, 1.61, and 1.81, with serum phosphorus of 5.0–5.99, 6.00–6.99, and  $\geq 7.0$  mg/dL, respectively [229].

## Vitamins

The recommended dietary intake of vitamins for MHD patients is shown in Table 31.3.

### Causes of vitamin deficiencies in maintenance hemodialysis patients

The causes for vitamin deficiencies include (1) reduced food intake due to anorexia or comorbid conditions (e.g., sepsis, dementia, disseminated cancer, and emotional depression). (2) Prescription of low-phosphorous, low-potassium diets that restrict intake of foods that are higher in vitamin content, for example, fruits, vegetables, and fortified dairy products. (3) Dialysate losses of water-soluble vitamins. (4) Altered metabolism of certain vitamins, as is the case for pyridoxine (vitamin B6) and possibly folate. (5) Impaired synthesis, for example, impaired conversion in the failing kidney of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D. (6) Resistance to the actions of vitamins due to kidney failure (vitamin B6, vitamin D, and possibly folate). (7) Medicines that interfere with the actions or

metabolism of vitamins. (8) Possibly decreased intestinal absorption of vitamins (decreased absorption of riboflavin, folate, and vitamin D); this has been described in rats with chronic renal insufficiency. Some medications taken by MHD patients may also interfere with intestinal absorption of vitamins. (9) Finally, some MHD patients are so impoverished that they are unable to purchase foods containing sufficient amounts of all vitamins.

### **Water-soluble vitamins (vitamins B1, B2, B3, B5, B6, B12, and C)**

In the absence of vitamin supplements, MHD patients are at risk of developing deficiencies of water-soluble vitamins [230–234]. Patients who receive dialysis with high-flux dialyzers may also have a greater need for vitamin supplements, because these patients have higher losses of a number of water-soluble vitamins into dialysate [235]. Consequently, some investigators have recommended that MHD patients should routinely take folic acid and vitamin B supplements.

This is a controversial subject for which no clear consensus is available. Some studies report that MHD patients do not develop signs of vitamin deficiencies when followed for about 1 year without taking vitamin supplementation [236,237]. However, in some of these studies, it was not uncommon to find that mean blood measurements for some of the water-soluble vitamins decreased to near the borderline for low values. These findings make it very likely that the blood levels for some vitamins fell below the normal range in some patients.

It is important to note that many studies that suggest vitamin supplementation is needed were conducted in the 1960s and early 1970s when there was a much higher incidence of PEW in MHD patients [236]. However, some recent reports show that many MHD patients consume some vitamins in lower quantities than the recommended dietary allowances [238]. The foregoing data indicate that there is a small but persistent prevalence of deficiency for some water-soluble vitamins in MHD patients. At the present time, it is difficult to identify which MHD patients will develop vitamin deficiencies if they do not take vitamin supplements. The clinical condition of an MHD patient who is eating well may also change abruptly if the patient becomes ill, and the patient's vitamin intake from foods may fall. Moreover, if the patient receives medical attention for an illness, he/she may receive medicines that interfere with vitamin nutrition. Hence, such a person may suddenly develop a need for vitamin supplements.

Since water-soluble vitamins appear to be safe and not very expensive and it is often not possible to predict when MHD patients need vitamin supplements,

we believe a strong case can be made that multivitamin supplements should be offered to virtually all MHD patients. A case in point is the study by Kalantar-Zadeh et al. of 30 normal individuals who were compared with 30 MHD patients that were matched for age, gender and race [239]. Their food intake was assessed by FFQs. The findings indicated that MHD patients consumed statistically significantly lower amounts of vitamin C, potassium, dietary fiber, and lower amounts of some carotenoids, including cryptoxanthin and lycopene. This lower intake of vitamin C, fiber, and carotenoids may be atherogenic. The lower vitamin intake in these MHD patients may be the result of the restriction of their dietary phosphorous and potassium intake. Dietary restrictions in MHD patients may lead to reduced intake of fruit, vegetables, and milk, which may leave meat, fats starchy food (breads, crackers), and sugars as the main sources of their calories.

Oral vitamin C supplements may promote intestinal iron absorption and reduce the incidence of iron deficiency in MHD patients (see Chapter 38: Nutrition and Anemia in Chronic Kidney Disease) [240–243]. Folic acid supplements may reduce the elevated serum homocysteine levels that occur in ESKD (End Stage Kidney Disease) to normal or near-normal. Maximum homocysteine-lowering effects with folic acid occur at doses of 5–10 mg/day [244,245]. However, studies that examined the potential effects of folic acid supplementation on cardiovascular deaths or all-cause mortality have not shown significant benefits. Advanced CKD and ESKD patients in the HOST study were randomized to receive pharmacological doses of folic acid, pyridoxine HCl (vitamin B6), and vitamin B12 [246]. The patients receiving this vitamin mix, in comparison to those receiving placebo, did not show improvement in total mortality or cardiovascular mortality [246].

In MHD patients, serum or erythrocyte levels of thiamin (vitamin B1), riboflavin (vitamin B2), pantothenic acid, and biotin are usually normal. Case reports of Wernicke's encephalopathy in MHD and CPD patients due to thiamin deficiency have been published [247,248]. Niacin (vitamin B3) levels are usually normal, although Lasker et al. reported low niacin levels in MHD patients [236,237,249–251]. Pyridoxine (vitamin B6) is removed by HD and its metabolism appears to be altered in advanced CKD and ESKD patients [252,253]. These two factors result in an increased daily requirement for vitamin B6. A supplement of pyridoxine HCl, 5 mg/day, for nondialyzed advanced CKD and CPD patients and 10 mg/day for MHD patients appears to satisfy the daily requirement for vitamin B6 [253]. Vitamin C is recommended only at the daily allowance of 70 mg/day because of the risk of oxalate formation increases

progressively as vitamin C intake rises (refer to [Chapter 26: Vitamin Metabolism and Requirements in Chronic Kidney Disease and Kidney Failure](#)).

### **Fat-soluble vitamins (vitamins D, K, A, and E)**

Fat-soluble vitamins are not removed by HD. Nonetheless, there is often a need for supplements of some fat-soluble vitamins. Deficiencies of 25 CKD and MHD patients who do not take supplements of these vitamins (please also see [Chapter 23: Calcium, Phosphate, PTH, Vitamin D, and FGF-23 in CKD-Mineral and Bone Disorder](#), [Chapter 25: Vitamin D in Kidney Disease](#)).

### **Vitamin K**

Two classes of vitamin K compounds (phyloquinone that is vitamin K<sub>1</sub> and menaquinones that is vitamin K<sub>2</sub>) are primarily responsible for vitamin K activity [254]. Since MHD patients do not generally have evidence of vitamin K deficiency unless they have been eating poorly or were on antibiotics that suppress intestinal bacterial vitamin K synthesis, supplemental vitamin K is not recommended for routine use. Vitamin K supplementation is required in patients who have suppressed intestinal absorption of vitamin K by antibiotics while they are not receiving vitamin K parenterally. KDOQI guidelines state that “it is reasonable that patients receiving anticoagulant medicines known to inhibit vitamin K activity (e.g.: warfarin compounds) do not receive vitamin K supplements” [14]. Some observational studies have indicated that in patients with advanced CKD (stages 3–5) or MHD patients serum vitamin K<sub>1</sub> and K<sub>2</sub> were low [255,256]. It has been reported that vitamin K status should be evaluated by using serum dephosphorylated-uncarboxylated Matrix Gla Protein (MGP) (dp-ucMGP) to determine whether CKD 3–5D patients should receive supplemental vitamin K. Vitamin K enables normal calcification process to occur in bone and soft tissue and, therefore, prevents soft tissue and vascular calcification. However, at this time, there is insufficient evidence to recommend providing supplemental vitamin K to correct high levels of serum dp-ucMGP to reduce the risk of arterial calcification in MHD patients. Westenfeld et al. were able to reduce dp-ucMGP levels with vitamin K<sub>2</sub> supplements (45,135, or 360 µg/d) in a dose-dependent fashion [256]. Several reports have described ectopic tissue calcification in MHD patients who have high levels of serum dp-ucMGP levels [257]. In one study in MHD patients, treatment with pharmacological dose of vitamin K<sub>2</sub> (45 mg/day orally) for 1 year was found to prevent bone loss, where bone disease was characterized by bone turnover [258]. An inverse relationship between the frequency of bone fractures and plasma phyloquinone levels was reported in MHD patients. In this

study, serum Parathyroid Hormone (PTH) was high (> 300 ng/L) in patients with low plasma phyloquinone (vitamin K<sub>1</sub>) concentrations who also had an abnormally high apolipoprotein E phenotype [259].

### **Vitamin A**

MHD patients, including those undergoing HD for many years, have increased serum vitamin A levels [260–262]. Vitamin A–retinol-binding protein (RBP) transthyretin complex is large in size and, therefore, is not lost into hemodialysate [263]. The HD process, itself, for this reason does not decrease serum vitamin A levels, and many CKD patients also have increased vitamin A levels and, as with MHD patients, do not show evidence of vitamin A toxicity [263]. RBP, which is the carrier protein for vitamin A, is degraded in the kidney. In renal failure, serum RBP and, hence, serum vitamin A are elevated, presumably because of reduced degradation of RBP by the failed kidney. However, even an extensively diseased kidney may continue to degrade some RBP. This may explain why MHD patients who had bilateral nephrectomy appear to have higher serum retinol levels as compared to other MHD patients [264,265]. β-carotene, ubiquinol, and lycopene are reported to be lower in MHD patients [266]. Werb et al. showed a positive correlation between plasma vitamin A concentrations and both serum total cholesterol and triglyceride levels [267]. The hematocrit is reported to correlate with plasma vitamin A/RBP ratio in MHD patients which may be suggestive that vitamin A levels promote erythropoiesis [268].

Patients with advanced CKD or ESRD are prone to develop vitamin A toxicity even relatively small doses of vitamin A. MHD patients ingesting the modest doses of 7500–15,000 units/day of vitamin A [about 2250–4500 retinol activity equivalents (µg RAE) of vitamin A] have been described with hypercalcemia and elevated alkaline phosphatase levels [269]. By comparison the recommended dietary allowance for vitamin A is 900-µg RAE for men and 700-µg RAE/day for nonpregnant, nonlactating women [270]. For this reason, it is recommended that the daily vitamin A intake from food and supplements combined for MHD patients should not exceed the recommended dietary allowances of 900- and 700-µg RAE/day [270].

### **Vitamin E (alpha-tocopherol)**

HD removes little vitamin E and does not materially change serum vitamin E levels. Serum vitamin E has been reported to be low, elevated, or even unchanged in MHD patients [271–273]. Chazot et al. found that long-term MHD patients who had received HD for an average of 274 ± 35 (SD) months had serum vitamin E levels that were increased and not different from

10 age- and gender-matched patients who had received MHD for  $51 \pm 29$  months [274]. Data regarding red cell tocopherol concentrations in MHD patients are contradictory [271,275]. These findings in some MHD patients may reflect increased consumption of tocopherol, possibly due to oxidative stress or to a defect in the HDL-mediated transfer of tocopherol from plasma to RBC membranes. Cohen et al. showed that RBC tocopherol concentrations were low in MHD patients who had sustained hemolysis due to high dialysate chloramine concentrations. The Red Blood Cell (RBC) tocopherol levels increased after chloramine was removed from the hemodialysate [276].

A number of studies, including a metaanalysis, have examined the effect on MHD patients using vitamin E-coated dialyzer membranes, but results were inconclusive [277–279]. The SPACE study was a double-blind, prospective clinical trial of 196 MHD patients who were randomized to receive supplements of oral vitamin E (800 IU/day) for a median of 519 days or placebo [280]. The MHD patients assigned to vitamin E treatment displayed a reduction in adverse cardiovascular events (RR = 0.46) and myocardial infarction (RR = 0.30) [280]. The relative risk in the SPACE study for ischemic stroke, peripheral vascular disease was not significantly different between the groups. Smaller studies on vitamin E supplementation did not confirm these reductions in morbidity or mortality. The HOPE study did not show the clinical benefits in patients with mild-to-moderate CKD (serum creatinine equal to or greater than 1.4–2.3 mg/dL) that were observed in the SPACE study [281]. The participants in the HOPE study who received vitamin E were given 400 IU daily for a median of 4.5 years. In the HOPE study, there was no difference between the placebo- and vitamin E-treated groups in total mortality. There was also no difference in the relative risk of Myocardial Infarction (MI), death from cardiovascular causes, stroke, heart failure, hospitalizations due to heart failure between the two groups. Moreover, a follow-up analysis of the HOPE study and its extension (HOPE-TOO) indicated an increased risk of heart failure in those patients who continued to receive long term the vitamin E supplements [282]. Since advanced CKD and MHD patients are at increased risk for oxidative stress and adverse cardiovascular events and because a vitamin E intake of 15 IU/day seems to be fairly safe, it is reasonable to prescribe a vitamin E supplement of about 15 IU/day to these patients.

## Carnitine

Carnitine is synthesized by the liver and the kidneys and is also ingested in foods we consume. Carnitine facilitates the transfer of long-chain fatty acids (>10

carbon) into skeletal muscle mitochondria [283]. It is the free, unacylated carnitine that facilitates this transfer. Carnitine is necessary for muscle function as fatty acids are the major fuel source for muscle during both rest and mild-to-moderate exercise. Serum total carnitine levels are often normal in MHD patients, but free carnitine levels are usually below normal and acylcarnitine (fatty acid carnitine esters) levels are elevated [284]. Free carnitine levels in skeletal muscle are often, but not always, low in MHD patients [285,286].

Some but not all studies of L-carnitine supplementation in patients with renal failure reported increased blood hemoglobin levels, reduction in such intradialytic symptoms as hypotension and muscle cramps, and decreased hyperlipidemia [287,288]. L-Carnitine has also been reported to increase skeletal muscle exercise capacity, improve sense of well-being, and reduce post-dialysis asthenia and malaise [289–291].

One randomized double-blind prospective clinical trial reported that L-carnitine decreased predialysis serum urea, creatinine, and phosphorous concentrations and increased mid-arm muscle circumference [290,291]. Interpretation of these data must be qualified because a number of outcome measures that showed improvement are imprecise or difficult to quantitate, not all randomized blinded studies showed benefits, and a number of the studies reporting benefits were not randomized, prospective, or blinded. With L-carnitine treatment, some clinical trials show improvement in serum lipid profiles but some clinical trials did not show benefit, and some studies reported an increase in serum triglyceride levels [292,293]. Due to these conflicting results, the therapeutic value of L-carnitine for MHD patients cannot be considered established. On the other hand, a number of blinded prospective studies did show benefits, and L-carnitine appears to be safe to be used in MHD patients [294,295].

While we await more definitive data, L-carnitine might be considered for use in the following clinical situations when all standard treatments have not resolved the problem:

1. anemia that is resistant to erythropoiesis-stimulating agents, iron, and vitamin therapy and with no evident cause;
2. intradialytic hypotension or muscle cramps;
3. impaired skeletal muscle exercise capacity;
4. postdialytic asthenia or malaise.

Before prescription of L-carnitine is given for the previous conditions, a thorough medical evaluation for other treatments should be conducted. The optimal dosage and route for therapy for L-carnitine are not defined at this time. The US Center for Medicare and Medicaid Services has recently approved coverage for use of L-carnitine for MHD patients if they have low plasma-free carnitine

levels ( $<40 \mu\text{mol/L}$ ) and either erythropoietin-resistant anemia or hypotension during HD. Continued coverage of L-carnitine treatment is not given unless improvement can be demonstrated. L-Carnitine can be given intravenously at a dose of 10–20 mg/kg given three times per week at the end of each dialysis session or it can be given orally at a dose of 5–10 mg/kg/day.

## Management of protein-energy wasting in maintenance hemodialysis patients

### ***A general approach to an maintenance hemodialysis patient with protein-energy wasting***

Patients who show evidence of PEW or at high risk of developing PEW may be managed with the following steps to prevent or treat this condition:

1. Perform a thorough medical and social history, physical examination, psychological evaluation, and protein-energy (nutritional) assessment as indicated in [Tables 31.1](#) and [31.2](#).
2. Identify the causes of the declining nutritional status. This assessment should include evaluating intake of dietary protein, energy, and other nutrients (e.g., using Urea Nitrogen Appearance (UNA) and dietary interviews and food dairies), examine for the presence of acute illnesses, exacerbation of established comorbid illnesses, nonspecific inflammation (e.g., an isolated increase in CRP), and acidemia. The causes for reduced food intake and acidemia should be investigated. Reduced intake of a healthy diet, for example, could be caused by anorexia which, in turn, may be due to inadequate dialysis dose or psychological depression. Other causes of reduce dietary intake are poverty, poor dentition, or inadequate social and family support. The patient's nutritional requirements should be evaluated.
3. Prompt therapy of any treatable comorbid condition (e.g., chronic infection, emotional depression with anorexia) that may contribute to PEW.
4. Counsel the patient and spouse or significant partners, and other members of the patient-family unit concerning the appropriate nutritional intake for the patient and strategies to attain it.
5. If the nutrient intake is inadequate in spite of appropriate dietary counseling, the following interventions may be employed:
  - a. Provide frequent high-energy, high-protein foods, food supplements, or supplements of specific nutrients (e.g., multivitamins, calcium iron, and zinc). If dietary adherence is questionable, these foods and supplements at least can be provided in the HD unit on the HD day.
  - b. Tube feeding.

- c. Intradialytic parenteral nutrition (IDPN) (see [Chapter 45: Intradialytic Parenteral Nutrition, Intraperitoneal Nutrition, and Nutritional Hemodialysis](#)).
- d. Daily total parenteral nutrition (TPN).

### ***Oral nutritional supplements, tube feeding and intravenous nutrition for patients with inadequate food intake***

#### **Oral nutritional supplements**

Nutritional status has been shown to improve when dietary counseling and oral nutritional supplements (ONS) are given to MHD patients who have PEW [\[296–298\]](#) (see [Chapter 44: Oral and Enteral Supplements in Kidney Disease and Kidney Failure](#)). A review of the evidence that nutritional support can improve protein-energy status, reduce PEW, and decrease the mortality risk in MHD patients has recently been published [\[299\]](#). A minimum of 3 months trial of ONS is suggested in patients at increased risk for PEW or with PEW [\[14\]](#). Studies have shown benefits from one can of a nutritional supplement given three times a week during HD session [\[300\]](#). ONS, such as Ensure and Boost, are rather inexpensive and can be recommended for patients who do not have hyperkalemia or volume overload. For patients who have a history of hyperkalemia or volume overload, low-potassium, low-phosphorus supplements, such as Nepro, or Novasource Renal, can be recommended as they have 30%–35% less potassium and phosphorus content per mL and double the amount of calories and protein.

#### **Tube feeding**

It is important to recognize that long-term compliance to ONS by MHD patients is low, in part, because these patients are usually financially constrained, and, in many countries they must purchase the ONS. In the authors' experience, even when MHD patients are given ONS at no cost to themselves, only about 20%–40% of these patients will take them on a continuing basis for several or more months. MHD patients often tire of these supplements.

Patients who, despite dietetic counseling, will not ingest adequate nutrients, even with ONS, may be considered for tube feeding. Tube feeding may be more effective and less expensive [\[301,302\]](#). It has been shown to be effective in pediatric patients receiving chronic dialysis. More studies are needed evaluate the effects of tube feeding on clinical outcomes, especially in adult CKD and chronic dialysis patients.

#### **Intradialytic parenteral nutrition**

IDPN is discussed in more detail in [Chapter 45, Intradialytic Parenteral Nutrition, Intraperitoneal](#)

TABLE 31.6 Intradialytic parenteral nutrition (IDPN) advantages and disadvantages in maintenance hemodialysis patients.

IDPN	
Advantages	Disadvantages
<ul style="list-style-type: none"> <li>• Can give hyperosmolar, concentrated admixtures through the extracorporeal circuit during the HD session</li> <li>• Noncompliant patients and patients who have poor appetite can receive nutrition as IDPN is given during hemodialysis session</li> <li>• IDPN can overcome gastrointestinal function disorders in HD patients like gastroparesis</li> <li>• The exact dose of nutrients can easily be calculated and administered</li> <li>• The amount of fluids delivered with nutrients can be removed simultaneously by the hemodialysis procedure</li> </ul>	<ul style="list-style-type: none"> <li>• Since dialysis is usually three times a week, IDPN can be given only three times a day limiting this therapy to only 3 days a week</li> <li>• Intravenous infusion of nutrients in a relatively short-time interval which may limit the efficient utilization of nutrients</li> <li>• It is more expensive than oral supplements</li> <li>• Nurses' workload is increased</li> </ul>

HD, hemodialysis.

Nutrition, and Nutritional Hemodialysis. Although IDPN is insufficient to meet, by itself, the energy and protein needs of normal MHD patients or MHD patients with PEW, it can be considered as a nutritional supplement when an adequate trial of oral supplements and tube feeding (enteral nutrition) have not eradicated or improved protein-energy status or when PEW appears to be worsening [14]. When patients have barriers to ONS or tube feeding (e.g., patient resistance to ONS or tube feeding, loss of sense of taste, logistical problems), IDPN can be considered earlier in the treatment strategy. To provide adequate nutrition, IDPN must be given with some other source of nutrients, for example, some oral intake of foods or ONS or some amount of tube feeding.

IDPN offers both advantages and disadvantages (Table 31.6). It is convenient to give the intravenous solutions during HD which removes the issue of compliance, although about 30% of the amino acids provided by IDPN are lost into dialysate. It is also important to note that studies have shown significant losses of amino acids in a regular HD session in MHD patients who are not receiving IDPN [5,6,303]. Wolfson et al. found that  $12.6 \pm 3.6$  SD g of amino acids were lost when MHD patients received an intravenous infusion of 39.5 g of amino acids during HD using inefficient hemodialyzers [5]. On the other hand, Ikizler found amino acid losses during high-flux HD of  $8.0 \pm 2.8$  g when patients did not receive IDPN [6]. Thus the increase in amino acid, losses during HD with IDPN, as compared to HD in the fasting state, is quite modest.

Although IDPN is probably helpful in some patients, many case reports and studies which reported benefits with IDPN were not well designed and did not have sufficient statistical power to offer firm conclusions.

IDPN solutions are prepared from base solution components. The base solutions for carbohydrates, amino acids and lipids can vary in concentration. Trace elements, vitamins, and minerals can be added to IDPN. The base solution from which a typical IDPN solution is prepared contains typically 40%–50% glucose, 10% amino acids and 10%–20% lipids.

### Total parenteral nutrition

When MHD patients are unable to eat and cannot be nourished by tube feeding, usually because they have undergone surgery or developed acute catabolic illness, they frequently must be given TPN to satisfy their daily nutritional requirements. TPN often must be modified extensively, because MHD patients have limited tolerance for nitrogenous products, water, and many minerals, especially when they are acutely ill. The principles and techniques of nutritional support for MHD patients are similar to the methods used in acute kidney injury (AKI) as discussed in Chapter 35, Metabolic Management and Nutritional Support in Acute Kidney Injury. Nutritional support during the treatment of kidney failure patients with continuous renal replacement therapy is discussed in Chapter 46, Nutritional Management of Patients Treated With Continuous Renal Replacement Therapy.

### Pharmacological agents to improve protein-energy status

#### Megestrol acetate

Megestrol acetate is a progestational agent that has been shown to improve appetite, food intake, and edema-free body weight in patients with carcinomatosis or AIDS [304–306]. However, in patients with

AIDS the increase in edema-free body weight was due to the accumulation of body fat rather than protein gain. There are currently no data in large-scale clinical trials that demonstrate that megestrol acetate improves appetite or protein-energy status in anorectic and protein-energy wasted MHD patients although small studies show trends toward some benefit [307–309].

### **Recombinant human growth hormone and insulin-like growth factor-I**

Several small clinical trials have examined a possible beneficial role of GH or IGF-I in advanced CKD and MHD patients [310–314]. GH administration can reduce net protein catabolism and wasting, improve nutritional status, and decrease SUN levels in MHD patients. This benefit is largely or entirely mediated by an increase in IGF-I levels. However, significant long-term nutritional benefits of GH are not consistently observed, and the effects of GH and IGF-I on morbidity and mortality are not clear at this time [315–318]. Patients with advanced CKD exhibit resistance to both GH and IGF-I [310,319]. However, pharmacological doses of these agents still exert their effects on catabolism, growth, and hyperfiltration. Adverse effects of GH include hyperglycemia and, in large doses, acromegaly. Administration of GH to critically ill patients should be avoided, as it may increase mortality [320]. Additionally, in the doses currently used, IGF-I can cause hypoglycemia; when given intravenously, IGF-I may cause cardiac arrhythmias [313].

Zeigler et al. gave GH, 5–10 mg subcutaneously after each HD, to five MHD patients for 2 weeks [321]. They were prescribed a fixed protein and calorie diet. The serum urea decreased by 20%–25%. Schulman et al. treated seven malnourished MHD patients with IDPN for 12 weeks [322]. During the last 6 weeks, they also received GH with each dialysis. With GH treatment the PNA decreased from  $0.81 \pm 0.04$  to  $0.67 \pm 0.03$ -g protein/kg/day, and there was an increase in serum albumin levels. Kopple et al. studied six MHD patients in a research ward for up to 35 days [323]. After a baseline period up to 14–21 days, the patients were administered 0.05-mg GH/kg body weight/day for  $17 \pm \text{SEM } 2$  days. Two participants, patients 3 and 4, experienced an acute illness during the study that resulted in a reduction in their protein and energy intakes. With GH treatment, predialysis serum urea fell markedly in patients 1, 2, 5, and 6 and to a much lesser degree in patients 3 and 4. Nitrogen balance was robustly positive in patients 1, 2, 5, and 6 but was less so in patients 3 and 4 [323]. The foregoing data indicate that GH induces an anabolic response in MHD patients with PEW [324].

### **Frequent hemodialysis, longer hemodialysis sessions, biocompatible dialyzer membranes**

A number of modifications of standard HD therapy have been investigated to improve the clinical status of MHD patients. This modification includes longer duration and/or more frequent HD sessions, including both daily (quotidian) and nocturnal HD [325–328]. Longer HD sessions are usually conducted for about 6–8 hours per session, often with lower blood flow rates at 200–250 mL/min [329]. More frequent HD sessions are usually conducted 5 or 6 days a week with lower blood flow rates of about 200–300 mL/min and dialysate flows of approximately 200–300 mL/min [330]. Biocompatible HD membranes, which are commonly high-flux membranes, are commonly used [331]. It is thought that these modifications in the traditional basic HD techniques of longer or more frequent HD treatments or more biocompatible membranes may reduce the severity of uremic symptoms and inflammation. Daily HD and nocturnal HD also allow MHD patients to have a less restrictive protein, mineral, and water intake [332,333].

# Nutritional management of chronic peritoneal dialysis patients

Carla Maria Avesani<sup>1</sup>, Olof Heimbürger<sup>1</sup>, Peter Stenwinkel<sup>2</sup> and Bengt Lindholm<sup>1</sup>

<sup>1</sup>Division of Renal Medicine—Baxter Novum, Department of Clinical Science, Intervention and Technology, Karolinska Institute, Stockholm, Sweden <sup>2</sup>Department of Nephrology M99, Karolinska University Hospital, Stockholm, Sweden

## Introduction

Peritoneal dialysis (PD) is based on the concept that the peritoneum may serve as a natural wearable inherent semipermeable membrane and dialyzer for removing solutes and water on a daily basis. A major advantage is that PD does not require blood access and that the gentle dialysis procedure results in steady, low metabolite levels, and steady control of fluid status without the rapid fluctuation in plasma solutes and fluid that occurs with hemodialysis (HD).

The dialysis solution is periodically instilled and drained from the peritoneal cavity through a PD catheter and is performed at home by the patient or by a caregiver after receiving careful training. The most common modalities of PD are continuous ambulatory PD (CAPD) and automated PD (APD). CAPD is performed manually with three to five exchanges per day. Each exchange has 1.5–3.0 L and the dwell time varies from 4 to 10 hours. The APD is performed by a cycler at night usually with 3–9 exchanges (cycles) over a period normally of 8–12 hours. Depending on the clinical needs of each patient, in addition to the APD, a manual exchange may be performed during daytime.

Different from the treatment with chronic HD, which is normally performed three times per week in a dialysis clinic, PD is usually performed at home every day. Because of its continuous nature, PD provides better metabolic control of mineral, fluid, and hydration status. On the other hand, since the dialysis fluid, in most cases, contains glucose as the osmotic agent, nutritional disadvantages may occur from the glucose absorption,

depending on the clinical and nutritional condition of the patient. Indeed, it is estimated that 40%–60% of glucose in the dialysate is absorbed, which yields approximately 300–450 kcal/day depending on the dialysis modality, the glucose concentration of the dialysate, the dwell time of the dialysate in the peritoneal cavity, and the transport characteristics of the peritoneal membrane [1]. In addition to glucose absorption, the protein losses that occur during PD treatment, due to the size of the peritoneal membrane pores, confer another nutritional disadvantage leading to lower serum albumin concentrations [1]. Also of importance, a significant proportion of patients with end-stage renal disease (ESRD) are aged 65 years and older, and the mean age of the individuals undergoing dialysis has increased substantially over the years [2]. Therefore particularities related to aging also require special attention when treating the nutritional aspects of PD [3]. This chapter reviews briefly the nutritional aspects of PD and describes the nutritional needs and strategies to prevent and treat the main nutritional disturbances that occur in PD patients.

## Main nutritional disturbances in patients undergoing peritoneal dialysis

The nutritional disturbances that are most prevalent in PD patients are protein-energy wasting (PEW), sarcopenia, and obesity with estimated prevalences as described in Table 32.1. A summary of other nutritional issues related to the modality of PD, as well as suggested nutritional interventions, are presented in Table 32.2.

**TABLE 32.1** Estimated prevalence of protein-energy wasting, sarcopenia, and obesity in peritoneal dialysis patients.

	Prevalence (%)	Study
Protein-energy wasting <sup>a</sup>	39–49	Carrero et al. [4]
	35.6	Vasselai et al. [5]
	22	Young et al. [6]
	19	Melo et al. [7]
Sarcopenia <sup>b</sup>	11	Abro et al. [8]
	10	Kamijo et al. [9]
	11.5	As'habi et al. [10]
Obesity <sup>c</sup>	15.6	Vasselai et al. [5]
	13	Fernandes et al. [11]
	36.5	Obi et al. [12]
	17.4	Prasad et al. [13]

<sup>a</sup>Assessed by subjective global assessment or malnutrition inflammation score.<sup>b</sup>Defined as low muscle mass and low muscle strength.<sup>c</sup>Defined as body mass index  $\geq 30$  kg/m<sup>2</sup>.**TABLE 32.2** Main nutritional disturbances in peritoneal dialysis and suggested nutritional interventions.

Nutritional disturbance	Nutritional intervention
1. Spontaneous body weight loss/malnutrition/sarcopenia	Consider counseling more frequent meals with small content of food per meal  Eat meals in between the dwell exchanges when the peritoneal cavity is empty. Some patients complain of early satiety due to higher intraperitoneal pressure with fluid in peritoneal cavity  Consider using energy and/or protein supplements (oral drinks or powders) to increase total energy and protein intake  Evaluate dialysis adequacy and adjust the dialysis dose when needed
2. Protein loss in the dialysate/hypoalbuminemia	Evaluate if protein intake is matching the protein needs  Add extra-sources of protein into meals (e.g., egg white, whey protein)
3. Early satiety	Avoid drinking liquids with meals  Preferably, eat meals in between the dwell exchanges
4. Obesity	Reduce the intake of foods rich in fat and sugar  Increase physical activity (under supervision)

(Continued)

**TABLE 32.2** (Continued)

Nutritional disturbance	Nutritional intervention
	Replace some of the exchanges with glucose-based solutions with icodextrin- and/or amino acid-based solutions
5. Hypertriglyceridemia	Reduce the intake of foods rich in sugar  Reduce the glucose concentration of the dialysate and replace some of the exchanges with glucose-based solutions with icodextrin- and/or amino acid-based solutions, if available  Increase physical activity (supervision)
6. Hypercholesterolemia	Reduce the intake of foods rich in saturated fat and trans-fat  Treatment with statins or other cholesterol lowering drugs  Increase the intake of fiber (grains, vegetables, and fruits)
7. Intestinal constipation	Increase the intake of fiber (grains, vegetables, and fruits) and water  Increase the use of vegetable oils (olive or linseed)
8. Hypokalemia	Increase the intake of grains, vegetables, fruits, and nuts
9. Hyperphosphatemia	Avoid the use of foods with a high-ratio phosphorus (mg)/protein (g) (e.g., dairy products, sardine, and liver)  Combine the use of phosphate binders with the meals or snacks with food sources of phosphate  Adjust the dose of phosphate binders according to the amount of phosphate in the meal  Treat hyperparathyroidism

### Protein-energy wasting, malnutrition, and sarcopenia

PEW was defined by an expert panel of the International Society of Renal Nutrition and Metabolism (ISRNM) as a “state of decreased body stores of protein and energy fuels (that is, body protein and fat masses)” [14]. PEW can be caused by a number of factors, including (1) insufficient food intake characterized by decreased intake of energy, protein, and other nutrients; (2) increased net protein catabolism and energy expenditure, due to low grade inflammation, acidemia, activation of

**TABLE 32.3** Etiological factors of protein-energy wasting specific to peritoneal dialysis (PD).

Outcome	Specific PD etiological factors
Low appetite and decreased energy and nutrient intake	Glucose absorption from the dialysate
	High intraabdominal pressure
	Inflammation
Increased protein catabolism	Inflammatory factors
	Peritonitis
	Nonbiocompatible dialysate solutions
Loss of nutrients in the dialysate	Amino acids and peptides: 3 g/day
	Protein: 5–15 g/day
	Vitamins B and C

Note: PD patients lose into dialysate water-soluble vitamins plus to some extent also fat soluble vitamins that are protein bound (due to the 5–15 g/day of protein losses into dialysate).

the ubiquitin–proteasome pathway, intercurrent catabolic illnesses such as peritonitis, hyperparathyroidism, and others; (3) nutrient losses into the dialysate, which play an important role in PD patients, as there are losses of amino acids, peptides, protein, and water-soluble vitamins into the dialysate; and (4) resistance to anabolic hormones (e.g., insulin, growth hormone, insulin-like growth factor 1, and testosterone) [15]. More recently, ageing [16] and a nonhealthy gut microbiota have also been suggested as nontraditional etiological factors for PEW and inflammation in chronic kidney disease (CKD) [17] (please see [Chapter 11: The Gut Microbiome and the Kidney](#), and [Chapter 13: Causes and Treatment of Protein-Energy Wasting in Kidney Disease](#)).

PD-specific factors involved in the etiology of PEW are depicted in [Table 32.3](#). Decreased appetite, a common condition in PD patients, seems to be an important factor [6]. Of note, a study comparing hunger, fullness scores, and energy and protein intake between PD and healthy individuals indicated that patients undergoing PD showed significantly lower sensations of hunger before meals and a flatter sense of fullness profile during the day, indicating lower feelings of hunger throughout the day. These PD patients also displayed a lower energy and protein intake [18]. Altogether, these findings are suggestive that lower appetite can lead to malnutrition. Corroborating this hypothesis, Melo et al. [7] recently showed in a study of PD patients, comprising mostly APD patients, that those in the tertile with the lowest appetite score, as assessed by an appetite questionnaire, had significantly lower ratings in the 7-point subjective global assessment (SGA) score, handgrip strength, phase angle, lean body mass index (BMI), and fat mass index when compared to the tertile with the highest appetite.

The factors causing low appetite in PD patients are still under debate. Glucose absorption from the dialysate—an

involuntary energy input—was shown to account for 15%–26% of total energy intake in a group of PD patients [19]. This involuntary input of glucose and energy is metabolically equivalent to a “fed state or postabsorptive state,” and the normal physiological stimuli to enhance appetite, such as low serum glucose and insulin levels and high ghrelin levels, are attenuated [20]. Thus these processes most likely lead to low appetite and a reduced energy and nutrient intake, although in a cohort study the amount of glucose absorption from the PD fluid was not associated with lower energy or protein intake [21]. Another factor diminishing appetite in PD patients is the increase in intraabdominal pressure caused by the infusion of the dialysate in the peritoneal cavity. This can lead to abdominal discomfort and increase satiety, mainly in patients treated with CAPD who perform dialysate exchanges during the day [20]. Indeed, Hylander et al. [22] showed that patients undergoing CAPD had a tendency to be less hungry before lunch when there was dialysate solution in the abdomen as compared to when the abdominal cavity was empty of dialysate. Finally, increased serum levels of proinflammatory markers have been reported in PD patients with decreased appetite [23]. Proinflammatory cytokines are well-described anorectic agents, and these findings suggest that inflammation may be another cause of decreased appetite in PD patients. The pathways explaining this association are not clear, but the anorectic actions of inflammation most likely include both decreased motility of the gastrointestinal tract and an increase in serum leptin levels, an anorectic hormone [20]. We reported a significant direct association between serum leptin and C-reactive protein concentrations in PD patients [24]. Altogether, PD patients are prone to the development of protein wasting, which is characterized by a condition of decreased protein mass (i.e., skeletal muscle mass) that is not necessarily accompanied by decreased fat stores (i.e., body fat).

In this regard, it is also important to describe sarcopenia, understood as another nutritional disorder defined as the loss of muscle mass and muscle function (i.e., low muscle strength and/or physical performance) (see [Chapter 12, Assessment and Risk Factors for Protein–Energy Wasting and Frailty in Chronic Kidney Disease](#), and [Chapter 13: Causes and Treatment of Protein-Energy Wasting in Kidney Disease](#)). Sarcopenia was initially described as occurring primarily from aging, and this has been referred to as *primary sarcopenia* [25]. However, in individuals with organ failure, such as in CKD, sarcopenia may occur in younger adults, independently of the aging process. Therefore, the European Working Group on Sarcopenia in Older People (EWGSOP) suggests the use of the term *secondary sarcopenia* when it is due to causes other than aging [25]. PEW and sarcopenia share many interlinked etiologic factors and diagnostic criteria; both are associated with poor clinical outcomes [26].

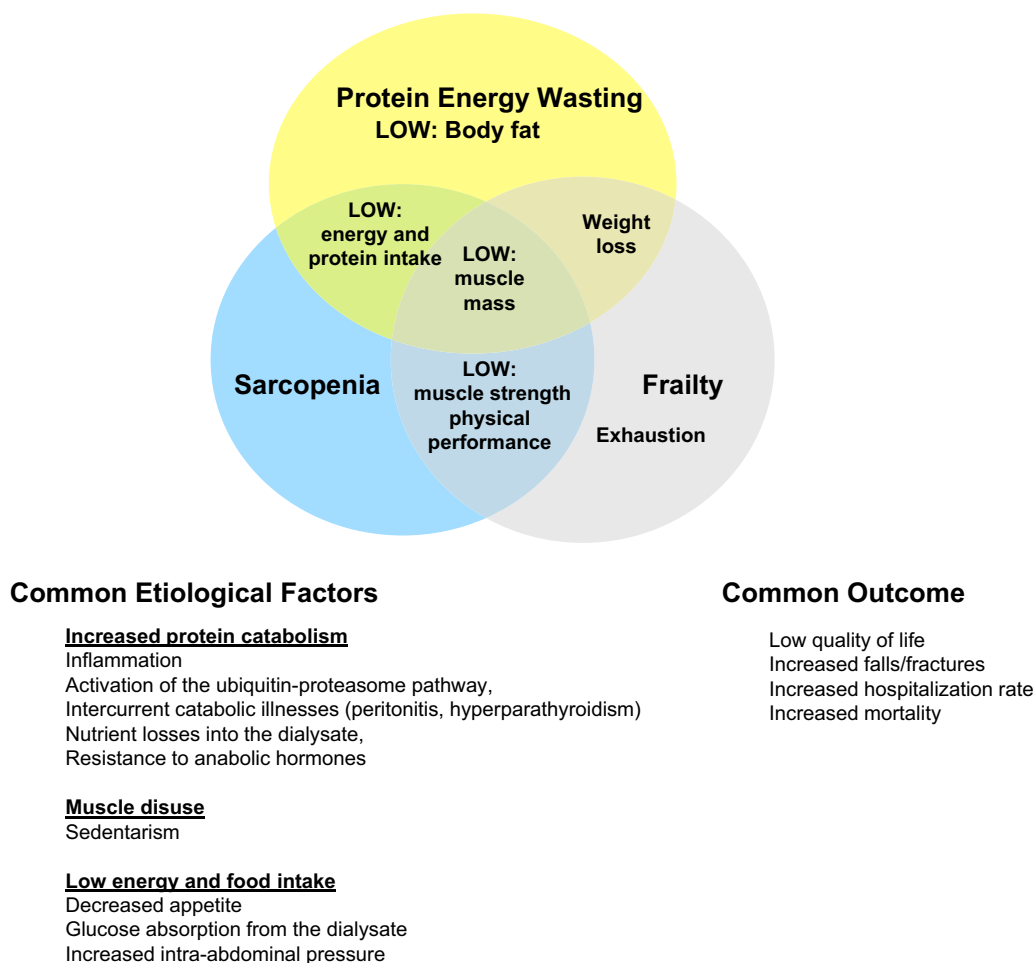

Frailty is a disorder commonly associated with PEW and sarcopenia (see [Chapter 12: Assessment and Risk Factors for Protein–Energy Wasting and Frailty in Chronic Kidney Disease](#)). Frailty is defined as a physiologic state of increased vulnerability to stressors that results from decreased physiologic reserves or dysregulation of multiple physiologic systems [26]. The clinical importance of frailty is that it is associated with poor clinical outcomes, due to a state of increased vulnerability, disability, dependence, falls, and institutionalization. Hence, frailty often results in hospitalization, poor quality of life, and increased risk of death. Frailty shares several common etiologic factors, criteria, and outcomes with PEW and sarcopenia [26]. The interconnection among these conditions is summarized in [Fig. 32.1](#).

## Obesity

Obesity is another common nutritional disorder in PD [5,11–13]. Most studies assessing its prevalence used BMI

of 30 kg/m<sup>2</sup> or greater as the indicator of obesity (as proposed by the World Health Organization). However, although BMI is simple and useful, it is highly influenced by the hydration status, and, therefore, may misdiagnose individuals with fluid retention as being obese. In addition, BMI cannot differentiate between the lean body mass and fat mass components of body weight and is not able to evaluate the distribution of body fat [27]. The limitations of using BMI as an obesity marker might have contributed a debate whether obesity is a protective factor for mortality.

The so-called obesity paradox, much discussed in the early 2000s, refers to the association between an increased body weight for height, or elevated BMI, and a lower hazard ratio for mortality in chronic dialysis patients. This relationship was first described in the late 1990s [28] and has been confirmed subsequently in HD patients [29]. Of note, Kalantar-Zadeh et al. [30] reported that HD patients with body fat mass between 24% and 36%, estimated from rear-infrared reactance, had lower risk of mortality when compared to those

**FIGURE 32.1** The common etiologic factors, criteria, and outcomes among protein energy wasting (PEW), Sarcopenia and Frailty are illustrated in this figure (Venn diagram). Of note, low muscle mass is a common diagnostic criteria for the three conditions.

with body fat below 12%. Moreover, in a subgroup of patients subsequently assessed after 6 months, a body fat gain greater than 1% was associated with lower mortality risk when compared to patients that had a decrease of more than 1% of body fat [30]. However, more recently, in a cohort of 5904 incident HD patients, the mortality risk was reduced in patients with a high BMI who had inflammation, but not in those who did not have inflammation [31], suggesting that reduced mortality risk may depend on whether inflammation is present. In PD patients a relation between high BMI and lower mortality risk was observed in some studies [12,32], but not in others [13,33,34]. The different length of follow-up, prevalence of diabetes, cardiovascular disease, the presence of persistent inflammation, and distinct levels of solute clearance in these studies might account for these conflicting findings.

While one can make a cogent argument that ESRD patients should not be allowed to become markedly obese or remain obese, several studies suggest that obesity is epidemiologically associated with reduced mortality in ESRD patients. However, Ramkumar et al. [35] found that the amount of muscle mass, rather than BMI, was associated with lower mortality in PD patients. That said, although increased BMI is epidemiologically associated with reduced mortality, obesity should not be understood as a protective factor for PD patients, but rather—and especially abdominal obesity—as a condition that can lead to other disorders, including metabolic syndrome, cardiovascular disease, inflammation, faster decline in residual renal function, and longer time to kidney transplantation [12,34,35]. In fact, Obi et al. [12] have reported in a large cohort of PD patients that higher BMI was associated with shorter intervals until HD transfer, longer time to kidney transplantation, and although not significant, a tendency toward higher frequency of peritonitis. Also of note, obese PD patients had faster decline in residual renal function and lower total Kt/V [36]. In addition, some studies have shown that PD patients with higher body weight and body fat gains after initiation of PD showed more unfavorable metabolic results, such as increase in blood pressure, edema, obesity, diabetes, and metabolic syndrome than those with lower body weight and less body fat gain [36,37].

The increase in body weight and body fat in PD seems to be more pronounced in the first year of treatment, and the risk factors associated with this finding are increased age, diabetes, high BMI, and genetic polymorphisms of the uncoupling proteins 1 and 2 [36–40]. An involuntary energy input from the glucose absorption in the dialysate could also be implicated, but no clear association has been found between higher glucose absorption and body weight

and body fat gain [5,36,39,40]. Altogether, it seems reasonable that obese patients undergoing PD with obese-related metabolic disorders and impaired quality of life should receive medical counseling with life-style changes, such as guided modification in dietary intake to their energy and protein needs and increased physical activity. The aim should be to ameliorate the metabolic disorders due to excessive body fat. Interventional studies testing the effects of these interventions in PD patients are still lacking. However, several studies, including randomized trials, demonstrate that the replacement of one exchange per day of a glucose-based dialysate with icodextrin-based dialysate resulted in a reduced body weight in the icodextrin group, whereas the patients using only glucose-based dialysate increased their body weight due to increased fat mass [41–43].

### Assessment of nutritional status in peritoneal dialysis patients

Due to the nutritional disorders commonly observed in PD, careful regular nutritional assessments are warranted. They should start when the patient is beginning dialysis and continue periodically throughout the course of PD treatments. The revised Kidney Disease Outcome Quality Initiative (KDOQI) Clinical Practice Guidelines for Nutrition in CKD [44] recommend the use of composite methods for evaluation, such as the SGA and the malnutrition inflammation score (MIS), to assess nutritional status and to screen for PEW in PD patients. These methods consist of a questionnaire with two sections, in which the first one evaluates the following domains of nutrition status: spontaneous loss of body weight, changes in appetite, gastrointestinal symptoms, occurrence of comorbidities, functional status, changes in dietary intake (amount and consistency) as well as current dietary intake, while the second section includes a careful physical examination, including assessment of fat stores, muscle loss, and the presence of edema [45]. The questionnaire is scored according to the clinical judgment of the examiner which preferably is performed by a dietitian. But other health-care practitioners, such as nephrologists and nurses, can also be trained to conduct this examination [45]. However, since these are subjective methods (and do not screen for obesity), it is desirable to complement SGA and MIS with objective methods that assess body composition, food intake, biochemical alterations, and muscle strength (Table 32.4).

Ideally, a complete nutritional assessment is performed at the beginning of the PD treatment and periodically as needed, except for body weight, which is usually recorded daily by the patients to assess the

TABLE 32.4 Suggested methods and their strengths and limitations to assess nutritional status in peritoneal dialysis patients.

Method	Strengths	Limitations
<i>Composite methods</i>	Provide assessment of five domains of nutritional status, ease of use, low cost, good predictive association with mortality and can be performed by trained clinical practitioners.	The scoring system is subjective to clinical judgment; large intra- and interexaminer variability; requires training; not suitable for screening for minor nutritional changes, or obesity. For MIS: uses laboratorial measurements and has no defined cutoff to classify malnutrition.
1. Subjective global assessment 2. MIS		
<i>Body composition</i>	Fast, low-to-medium cost, portable equipment, suitable for clinical practice.	Low-to-medium precision, subjected to intra- and interexaminer variability, influenced by hydration status. BIA: Measurements should be preferably made without dialysate in the peritoneal cavity. Results vary depending on the body composition software used in the equipment.
1. Anthropometry 2. BIA (single or multifrequency)		
3. DXA 4. CT 5. MRI	Good precision, assessment of fat distribution. DXA and MRI: provide measurements of whole-body composition as well as from body segments. CT and MRI: provide measurements of subcutaneous and visceral fat as well as intramuscular fat. Not influenced by fluid status.	High cost for acquiring and maintaining the equipment, requires technician to perform the exam, suitable for research setting. DXA: The assessment of lean mass is influenced by the hydration status. Therefore it should be preferably performed without dialysate in the peritoneal cavity. CT: exposure to radiation.
<i>Food intake</i>	Allows assessment of energy and nutrient intakes, food habits, food preferences, and aversions. Provides assessment of dietary quality and type of protein.	Subject to the patient's willingness to carefully report and remember food intake, difficult to estimate portion servings, estimation of energy, and nutrients are often underreported.
1. 24-h food questionnaire 2. Food registry 3. Food history 4. PNA	Objective method to estimate protein intake. Not subjected to patient under- or overreporting food intake.	Do not reflect protein intake if the patient is in a catabolic or anabolic state. Does not allow assessment of quality and type of protein ingested.
<i>Biochemistry</i>	Considered markers of inflammation with good prediction for mortality. CRP is a good marker of cardiovascular disease.	Albumin: Long median life; does not reflect nutritional status if inflammation is present or if there are large albumin losses into the dialysate (primarily if peritonitis is present). If hypervolemia is present, serum albumin values may be reduced due to dilution rather than to inflammation or protein-energy wasting.
1. Serum albumin 2. Serum CRP		
<i>Muscle function</i>	Measurement of muscle function, included in the criteria to diagnose sarcopenia and frailty, highly correlated with muscle mass, a good predictor of hospitalization and mortality.	Does not reflect whole-body strength.
Handgrip strength (handgrip dynamometer)		

BIA, Bioelectrical impedance analysis; CRP, C-reactive protein; CT, computed tomography; DXA, dual energy X ray absorptiometry; MIS, malnutrition inflammation score; MRI, magnetic resonance imaging; PNA, protein equivalent of nitrogen appearance.

need for ultrafiltration, and recommended by the updated Nutrition KDOQI guidelines to be assessed at least monthly as part of the follow-up of nutritional status [44]. Our clinical experience indicates the need for a complete nutritional assessment at least once every 6 months to screen for early changes in nutritional status. Of importance for PD patients, assessment of body weight, waist circumference, and body composition should be performed with their peritoneal cavity empty so that dialysate fluid will not influence the measurements.

### Nutritional counseling and recommendations for peritoneal dialysis patients

Patients undergoing PD treatment should receive specialized dietary counseling aiming to prevent and treat the nutritional disturbances commonly observed in this group of patients. Table 32.5 describes recommended energy, protein, and mineral intakes for PD patients according to different guidelines and consensus [44,46]. For the dietitian in clinical practice the main challenge is to convert these recommendations

**TABLE 32.5** Energy, nutrients, mineral, and liquids recommendations for peritoneal dialysis patients.

Energy/nutrient/mineral	Recommendation	Reference
Energy (kcal/kg/day)	25–35 <sup>a</sup>	[44]
Protein (kcal/kg/day)	1.0–1.2	[44]
	1.2–1.5	[46]
Potassium (mg/day)	Individualized to maintain serum potassium within the normal range. If hyperkalemia is present, consider lowering the dietary potassium intake to 2000–2500 mg/day	[44]
		[46]
Phosphorus (mg/day)	Individualized to about 800–1000 mg/day to maintain serum phosphorus within normal range	[44]
		[46]
Sodium (g/day)	<2.3	[44]
	1.8–2.5	[46]
Liquids (mL/day)	1000 + daily urine volume	[46]

<sup>a</sup>Individualized according to the patient's nutritional status and physical activity. The energy derived from the glucose absorbed from peritoneal dialysate should be considered part of the total prescribed daily energy intake as described in Box 32.1. BMI, Body mass index.

# For body weight: use the patient's current body weight (after drainage of fluid from the peritoneal cavity) if it is thought to be indicative of adequate nutritional status. If not, the body weight within a BMI range of 23–29.9 kg/m<sup>2</sup> is suggested by the authors due to the ease-of-use in clinical practice.

into a meal plan that is feasible for the patient and which, therefore, addresses such important aspects as socioeconomic and cultural factors and food habits and preferences. To achieve this goal the presence of a renal dietitian on the team that can dedicate the necessary time for planning, educating, and monitoring the patient during treatment is warranted [44].

Unfortunately, not all dialysis centers have the possibility to provide this kind of nutritional care, and low-dietary adherence is commonly reported. This has been shown in a metaanalysis assessing nonadherence to PD regimens (dialysis procedures, medication, and dietary fluid/restrictions). Of note, nonadherence to dietary fluid/prescription varied from 15%–67%, with a self-reported nonadherence to fluid restriction of 34%–56% [47]. Aligned with these findings, a study using 7 day–weighed dietary records, that is, food diaries where food to be ingested for a determined period are weighed using a kitchen food scale to improve precision in the portions recorded, showed that the mean energy and protein intake of PD patients was  $25.3 \pm 7.4$  kcal/kg and  $0.92 \pm 0.36$  g/kg (mean  $\pm$  SD), which is lower than that recommended in the nutritional guidelines [48]. It is important to

mention that these patients had a mean ratio of energy intake to resting energy expenditure of 1.22, meaning they were “good reporters” of their food intake. The factors associated with this nonadherence are diverse and include sociodemographic characteristics, medical treatment–related, issues and the number of individual contacts with health professionals [48]. To reduce the high rate of nonadherence to medical nutritional therapy, the use of a multidisciplinary and interdisciplinary team is desirable. Some of the specific issues relevant for PD patients are described later.

## Energy and fat

According to the updated Nutrition KDOQI guidelines [44], ESRD patients should be advised to follow a diet with 25–35 kcal/kg of body weight/day, depending on age, level of physical activity, body composition, weight status goal, and the presence of inflammation to maintain adequate nutritional status. For PD patients the involuntary energy input derived from the glucose absorbed from the dialysate should be taken into account. When estimating the energy needs of patients with either insufficient energy intake, spontaneous body weight loss, or PEW and sarcopenia, it is recommended not to deduct from the estimated total energy needs the energy derived from glucose absorbed from dialysate. However, if the patient is overweight or obese, not under body weight loss or with adequate energy intake, the involuntary energy load from the glucose absorption from the dialysate can be discounted from the estimated total energy needs.

The energy load derived from the glucose in the dialysate varies depending on the dialysis modality (CAPD or APD) and differences with regard to the frequency of exchanges and total volume of dialysis fluid used (thus there is usually a higher glucose load with APD), glucose concentrations of the infused dialysis fluid, and also patient factors such as peritoneal transport status (fast/high transporters have more rapid absorption), and need for ultrafiltration [49]. However, the percentages of the instilled amount of glucose that is absorbed from the three different dialysis fluids (1.36%, 2.27%, and 3.86%) in CAPD patients were, on average, almost identical, 63% and 75%, respectively, after 240 and 360 minutes: after a dwell time lasting 6 hours, the initial amount of intraperitoneal glucose absorbed corresponded to a mean ( $\pm$  SD) energy supply of  $75 \pm 6$ ,  $131 \pm 18$ , and  $211 \pm 26$  kcal for the three solutions (1.36%, 2.27%, and 3.86%), respectively [49]. In a study from Grodstein et al. [50], the daily energy supply in CAPD patients from dialysate glucose was  $8.4 \pm 2.8$  kcal/kg (mean  $\pm$  SD) of body weight per day, or 12%–34% of total energy intake. Table 32.6

**TABLE 32.6** Glucose concentrations and corresponding energy load in glucose-based peritoneal dialysis fluids, and the estimated energy input from glucose absorption from the dialysate.

Solution	Glucose monohydrate (g/L)	Glucose anhydrate (g/L)	mmol/L	Total energy load <sup>a</sup> (kcal/L)	Energy from glucose from a 2-L bag <sup>b</sup>
1.5%/1.36%	15	13.6	75.5	50	70 kcal/2 L
2.5%/2.27%	25	22.7	126	84	118 kcal/2 L
4.25%/3.86%	42.5	38.6	214	143	201 kcal/2 L

<sup>a</sup>0.67 kcal/mmol of anhydrous glucose.<sup>b</sup>Assuming that 70% of glucose is absorbed.

Please note that in some locations, including the United States, glucose content is expressed as the amount of glucose monohydrate (molecular weight 198.17 g/mol), whereas in Europe and other locations the amount of anhydrous glucose (molecular weight 180.156 g/mol) is stated (multiply dextrose monohydrate by 0.909 to obtain the amount or concentration of anhydrous dextrose). The corresponding concentrations are given earlier. The energy equivalent for glucose monohydrate is about 3.4 kcal/g and for anhydrous glucose about 3.7 kcal/g. On average, about 70% of the infused glucose is absorbed after 4–6 h during CAPD but differs according to the duration of the dialysis fluid exchange (63% at 4 h and 75% at 6 h), the patient's peritoneal transport group (higher absorption in fast/high transport patients), and other factors [49,51]. CAPD, Continuous ambulatory peritoneal dialysis.

**BOX 32.1**

**Example of how to calculate the estimated glucose absorption for a patient under treatment with continuous ambulatory peritoneal dialysis (CAPD) or automated peritoneal dialysis (APD).**

**CAPD**

1. Collect information on dialysis prescription of the patient. Example:  
3 bags of 2 L with 1.5% of glucose monohydrate (13.6 g/L of anhydrous glucose; multiply dextrose monohydrate by 0.909 to obtain the amount or concentration of anhydrous dextrose)  
1 bag of 2 L with 4.25% of glucose (38.6 g/L of anhydrous glucose)  
*Observation: Note that the dialysis fluid bags usually are slightly overfilled, and the overfill should be assessed for the brand of dialysis fluid used*
2. Calculate total glucose content according to the information described in [Table 32.6](#)  
 $6 \text{ L} \times 75.5 \text{ mmol/L} = 453 \text{ mmol}$   
 $2 \text{ L} \times 214 \text{ mmol/L} = 428 \text{ mmol}$   
 $\text{Total amount infused} = 453 + 428 = 881 \text{ mmol}$
3. Measure drained volume and glucose in drained dialysate  
Example drained volume 8750 mL and glucose concentration in drained dialysate 31 mmol/L gives drained glucose amount  $8.75 \text{ L} \times 31 \text{ mmol/L} = 271 \text{ mmol/L}$

4. Calculate amount of glucose absorbed and corresponding energy  
 $881 - 271 \text{ mmol} = 610 \text{ mmol} = 610 \times 0.67 \text{ kcal} = 409 \text{ kcal}$

**APD**

1. Collect information on dialysis prescription of the patient. Example:  
The volume of the infused dialysis solution is given by the APD cyclor
2. Calculate the total infused glucose
  - a. Multiply the total volume in L by the glucose concentration as earlier for CAPD
  - b. Sum up the total amount of glucose infused, as earlier for CAPD
3. Calculate the amount of glucose absorbed by measuring glucose in drained dialysate or approximate it to 30%–50% but differ due to dialysate flow rate, and the patients peritoneal transport group  
A mean of 40% could be used as an estimation of the glucose absorbed
4. Calculate the estimated corresponding energy load (kcal/day)

describes the glucose amount, energy load, and estimated energy input from the glucose absorption according to the glucose concentration in the solution. [Box 32.1](#) describes an example on how to calculate the estimated glucose absorption for a patient undergoing CAPD or APD.

Regarding fat intake, although there is no specific recommendation for PD patients, it seems reasonable to follow the recommendations from the American Heart Association dietary guidelines to control the plasma lipid profile [52]. According to this guideline, the total dietary fat should provide 25%–35% of the

total energy intake in which <7% of the energy is from saturated fat, more than 20% from monounsaturated fatty acids, and more than 10% of energy from polyunsaturated fatty acids (PUFA). The total intake of cholesterol should be <200 mg/day. In addition, the updated Nutrition KDOQI Guidelines recommend supplementation with 1.3–4 g/day of PUFA to improve the lipid profile [44].

Regarding dialysate protein-energy supplementation, the updated Nutrition KDOQI Guidelines [44] do not suggest substituting dextrose dialysate with amino acid dialysate as a general strategy to improve nutritional status. However, if energy and nutritional intake (by oral or enteral intake) is below the nutritional requirements, the use of peritoneal dialysate that contains 1.1% of amino acids may be considered to diminish protein deficits, as suggested in previous studies where an increase in serum albumin and anthropometric measurements of muscle mass were found in malnourished patients with the use of dialysate containing amino acids [53,54]. These findings were reported in randomized controlled studies in CAPD patients, in which one exchange of 1.5% dextrose dialysate was replaced by 1.1% amino acid dialysate daily from 3 months to 3 years [53,54]. It is important to mention that dialysate with amino acids is not available in many dialysis centers and, therefore, may not be a feasible clinical alternative.

## Protein

With respect to recommended dietary protein intakes, metabolic studies indicate that a protein intake of about 1.1 g/kg/day may be necessary to ensure neutral or positive nitrogen balance in virtually all clinically stable adult PD patients (as long as enough energy is provided) [21,55,56]. These data are consistent with other guidelines or consensus statements that the estimated protein needs of adult PD patients may vary from 1.0 to 1.4 g/kg/day [44,46]. Despite these variations in dietary protein recommendations, metabolic studies show that most patients can maintain neutral nitrogen balance with a protein intake close to 1.0 g/kg/day [21,55]. In theory, the dietary protein requirements of PD patients should be the same as for healthy individuals plus an added amount of protein corresponding to the increased nitrogen losses in the dialysate. These losses may be further enhanced by inflammatory and catabolic stimuli linked to the dialysis procedure (effect of the dialysate and catheters and especially if there are episodes of peritonitis) and to the numerous metabolic disturbances common in ESRD patients. Since the average loss of protein into dialysate is about 5–15 g/day [57], the daily protein intake of a

PD patient needs to be increased by around 0.1–0.2 g protein/kg/day for an adult weighing 60 kg. Therefore, at least in theory, the total protein requirements for PD patients would be approximately 1.0–1.2 g/kg/day. On the other hand, a high protein intake could make the control of phosphorus levels more difficult and might worsen the complications resulting from hyperparathyroidism, elevated FGF-23 levels, and a high plasma calcium–phosphorus product (see Chapter 17: Disorders of Phosphorus Homeostasis: Emerging Targets for Slowing Progression of Chronic Kidney Disease, Chapter 23: Calcium, Phosphate, PTH, Vitamin D, and FGF-23 in CKD-Mineral and Bone Disorder, and Chapter 24: Phosphorus Metabolism and Fibroblast Growth Factor 23 in Chronic Kidney Disease). Therefore the current recommendation from the updated Nutrition KDOQI Guidelines of 1.0–1.2 g/kg of body weight/day should provide an adequate amount of protein to cover the protein needs for most clinically stable PD patients while taking into consideration the amount of protein intake that is compatible with adequate phosphorous control [44].

## Phosphorus

This subject is discussed in Chapter 17, Disorders of Phosphorus Homeostasis: Emerging Targets for Slowing Progression of Chronic Kidney Disease, Chapter 23, Calcium, Phosphate, PTH, Vitamin D, and FGF-23 in CKD-Mineral and Bone Disorder, and Chapter 24, Phosphorus Metabolism and Fibroblast Growth Factor 23 in Chronic Kidney Disease, and can be used to further complement information on phosphorus metabolism, physiology and needs in this group of patients. A careful balance between the need to increase protein intake while restricting phosphorus intake should be considered when counseling PD patients with regard to diet, since most food sources of protein are also rich in phosphorus. A well-known dietary strategy to achieve the protein needs and, at the same time, not exceed the phosphorus intake is to educate patients regarding dietary choices [58]. The following can be advised:

1. To prevent or treat hyperphosphatemia, foods that have a high phosphorus (mg)-to-protein (g) ratio should not be eaten in large amounts. In general, dairy products (milk, yogurt, and cheeses), some types of meat (such as liver and other viscera), and some fishes (such as sardines) are examples of foods with a high phosphorus:protein ratio [57]. Those foods should not be excluded from the diet but rather ingested in small-to-moderate servings. It is also important to consider that the bioavailability of phosphorus from animal protein is higher than that from vegetable protein, indicating that there is a

higher absorption of phosphorus from animal protein in the gastrointestinal tract. In vivo studies show that gastrointestinal digestion and absorption varies from 53% to 78% of the phosphate in dairy products, from 73% to 89% of the phosphate in red meat and poultry, and less than 50% of phosphate in vegetables [59,60]. The explanation for this difference is that most phosphate in vegetables is bound to phytate, which is not well digested by humans due to the lack of the enzyme phytase in the intestine [61]. That said, vegetable protein can also be considered as a preferred source of protein in people with severe hyperphosphatemia.

2. If hyperphosphatemia is present, phosphorus-rich food sources especially those that are not rich in protein, such as beer, soft “cola” drinks, and chocolate, but also peanuts, other nuts, peanut butter, and almond butter, can be replaced with other foods with low phosphate content [58].
3. Finally, many additives used in processed and ultraprocessed food to increase shelf time and prolong the expiration date are composed of inorganic phosphate. A higher proportion of inorganic phosphate is absorbed by the gastrointestinal tract, and, therefore, the intake of processed foods containing inorganic phosphate provides a “hidden” source of phosphate that should be avoided [58]. Educating patients to read food product labels is a valid strategy to diminish the serum phosphorus level [62].
4. If phosphate binders are used to control hyperphosphatemia, it is important to combine its use at the times of meals that contain larger food sources of phosphorus, since the phosphate binders act in the gastrointestinal tract by forming a poorly absorbed, insoluble compound that is eliminated in the feces [58]. To increase the adherence to the prescribed dosage of phosphate binders, it is important to explain to patients how they work.

## Potassium

Dietary restriction of potassium is one of the most common foci of nutritional counseling for CKD and ESRD patients. The concern over hyperkalemia has led some clinical practitioners to the view that all high potassium foods (mainly fruits, vegetables, grains, and nuts) should be avoided. However, since these foods can contain substantial amounts of fiber, vitamins, and antioxidants, one should evaluate more carefully whether avoidance of these foods is indeed necessary. Restricting these food items can be harmful since this practice may generate a poor-quality diet with a reduced fiber content. This, in turn, can engender intestinal disorders, including

constipation, and an unhealthy gut microbiota that may increase plasma concentrations of proinflammatory cytokines [17,63,64].

In fact, a study, including PD patients, reported that 90% of these patients had a low-dietary intake of fiber (median fiber intake, 12.2 g/day). Patients with a fiber intake above the median ( $>12.2$  g/day) had significantly lower intraperitoneal levels of proinflammatory cytokines. However, in serum, only the cytokine monocyte chemoattractant protein-1 was lower than in the group with fiber intake below the median ( $<12.2$  g/day) [64]. Moreover, a recent study showed that dietary fiber [mean intake,  $8.2 \pm 3.4$  g/day ( $\pm$  SD)] was associated with lower all-cause mortality in nondiabetic PD patients [65]; however, further studies are needed to establish whether the fiber intake and lower mortality are causally related.

Therefore some conditions should be considered before restricting dietary sources of potassium: first, dietary potassium should be restricted only if hyperkalemia is present, which is not the case for all PD patients; hypokalemia ( $<3.5$  mEq/L) is almost as prevalent as hyperkalemia ( $>5.0$  mEq/L) in PD patients [66].

Second, even if hyperkalemia is present, it is important to investigate whether the patient has a high intake of potassium. Hyperkalemia can be caused by many factors, including decreased renal function, metabolic acidosis, hyperglycemia, intestinal constipation, use of renin–angiotensin–aldosterone system inhibitors, and low dialysis adequacy [63]. Therefore high dietary potassium intake may not be the cause of hyperkalemia, and potassium restriction may not treat the underlying condition and could lead to a harmful, poor-quality diet.

Third, if the patient has hyperkalemia and there is an increased potassium intake, there are fruits and vegetables with lower potassium content ( $<200$  mg/serving) that can be counseled to replace those with higher potassium content (Table 32.7). In addition, cooking vegetables in boiling water, with the vegetables unpeeled, and draining the water after they are cooked is a simple procedure that can diminish up to 80% of the potassium content of vegetables [67]. Although this procedure diminishes the content of water-soluble vitamins, it is still a valid procedure to allow the intake of vegetables in the diet of patients with hyperkalemia.

Finally, potassium additives are increasingly used not only in ultraprocessed foods but also in processed foods to diminish or replace sodium chloride [68]. Processed food refers to any food that has been processed by food industry and may, therefore, include uncooked food (as an example, uncooked meat, poultry, or fish; refined grains and other foods that are processed for packing purposes). Similar to phosphate,

**TABLE 32.7** List of fruits and vegetables with low and high content of potassium per serving.

Fruits	Raw vegetables
<b>Fruits and vegetables with low potassium content (&lt;200 mg/serving)</b>	
1 medium persimmon	5 lettuces leaf
1 medium slice of pineapple	1 cup of watercress
10 small strawberries	1 cup of sliced cucumber
1 medium apple	1 cup of cabbage
1/2 of medium mango	3 radishes
1 medium pear	1 medium paprika
1 medium peach	1 tomato
1 medium fresh plum	1/2 of medium carrot
1/2 cup of blueberry	1/2 cup of escarole
40 mL of lemon juice	
<b>Food with high potassium content (&gt; 200 mg/serving)</b>	
1 medium banana	1 cup of kale
1 slice of melon	3 spoon soups of beet
1 orange	2 tomatoes
1 tangerine	1 cup of broccoli
1 kiwi	
1/2 avocado	
coconut water from 1 coconut	
1 cup (cubes) of papaya	
10 grapes	
1 cup of cherries	
3 passion fruits	

potassium additives are a “hidden” source of potassium that is highly absorbed in the gastrointestinal tract [68]. Therefore foods with potassium additives should be restricted from the diet of PD patients. Star fruit, however, should be prohibited altogether from the diet of patients with ESRD not due to its potassium content, but due to a neurotoxin present in the star fruit that cannot be well depurated by dialysis [69]. Depending on the amount of star fruit eaten, intoxication can occur with symptoms of intractable hiccups, mental confusion, prolonged seizures, and, in severe cases, death [69].

## Fluids and sodium

Since PD is performed for many hours each day, it should be possible to obtain better fluid control than with HD patients. The fluid prescription (restriction)

should be individualized according to the patient’s urine output (if present) to maintain adequate fluid control with no edema. To achieve this, it is important to encourage patients to follow a low-sodium diet with very limited intake of ultraprocessed food (such as sausages, processed cheeses, chips, ready-to-go foods). The use of herbs and spices to replace or diminish the use of salt is a feasible maneuver to enhance taste and increase adherence to a low-sodium diet. Of importance, patients should be reminded not to use potassium chloride to replace regular salt (sodium chloride) when cooking, as this can increase serum potassium as mentioned before.

## Which body weight should be used to calculate energy and protein recommendation?

The determination of body weight is a central consideration for diet prescription. The desirable body weight which is used to calculate the dietary prescription is often calculated as the weight which is consistent with the patient’s normal BMI or the patient’s usual or current body weight. According to the updated Nutrition KDOQI Nutrition in CKD guidelines [44], the desirable body weight can be determined by clinical judgment concerning the patient’s health goals. It is important to evaluate whether the patient’s current body weight (without fluid in the peritoneal cavity) is indicative of adequate nutritional status. If so, the current body weight can be used to calculate the dietary prescription. However, if the current body weight is indicative of obesity (e.g., a BMI  $\geq 30$  kg/m<sup>2</sup>) or if the nutritional status is indicative of mild-to-severe malnutrition (according to SGA or MIS or BMI  $<23$  kg/m<sup>2</sup>), the body weight that reflects a BMI of 23–29.9 kg/m<sup>2</sup>, and which is closest to the patient’s usual body weight, has been proposed as the weight to be used for dietary prescription. The most important criteria for deciding the desirable body weight should be the patient’s nutritional condition and health goals.

## Healthy diet for peritoneal dialysis patients: an important concept that has been neglected in the renal diet

As a first principle for the dietary prescription for PD patients, the diet should be healthy. This means that the diet should enable long-term health. In addition to an adequate intake of macronutrients (protein, fat, and carbohydrates), and essential minerals and micronutrients (vitamins and trace elements), patients may benefit from the intake of bioactive nutrients; that

is, nonessential biomolecules present in foods that exhibit the capacity to modulate metabolic processes, thereby contributing to better health. Examples of such compounds are the phytochemicals (present in small amounts in plant foods such as fruits, vegetables, and grains) that may have beneficial effects by reducing inflammation, senescence, mitochondrial dysfunction, gut dysbiosis, and improving one-carbon metabolism. Taking into account the “foodome” (a new area of food science and nutrition aiming to analyze the effects of food on human health) and using “food as medicine” are new approaches likely to play an important future role to prevent the progression of kidney disease and reduce the risk of its complications [70]. A diet with many restrictions, with very limited intake of fruits, vegetables, grains, whole cereals, and nuts, is in direct contrast to a healthy diet and can induce the patient to follow a poor-quality diet with an increased intake of highly processed foods. Unnecessary dietary restrictions, such as unjustified restriction of food sources of potassium, should be discouraged. Instead, a careful meal plan that includes all food groups (cereals, mainly whole cereals; grains; fruits and vegetables; nuts; meat, preferably fish and poultry; eggs; vegetable; and fish oil) is encouraged.

Observational data suggest that patterns of chronic food intake similar to the Mediterranean Diet and the DASH Diet (Dietary Approach to Stop Hypertension) may reduce the incidence of CKD, decrease the progression of CKD to ESRD, and reduce mortality rates in CKD and maintenance HD patients [71–73]. These diets are characterized by a high intake of fruits, vegetables, grains, whole cereals, and moderate intake of lean meat (poultry and fish), eggs, and low-fat dairy products (milk, yogurt, and cheese). Although studies investigating the role of a healthier dietary pattern in PD patients are lacking, it seems reasonable to conclude that patients on PD may also benefit from such healthy dietary patterns.

As is emphasized in this chapter, even when dietary restriction of phosphorus and potassium are needed, dietary counseling should include healthy foods. Priority should be given to restricting processed foods that contain hidden sources of four undesirable elements of the renal diet: inorganic phosphate and potassium, which are both highly absorbed by the gastrointestinal tract, and sodium and poor-quality fat (i.e., saturated fatty acids, trans-fatty acids, and cholesterol). It is critical to encourage patients, family members, and/or the patient’s caregiver to buy fresh ingredients, cook, and use the mealtimes as enjoyable daily events. These activities are the key for long-term adherence to healthy and appropriate renal diets.

Finally, the need for vitamin supplementation due to deficient intake, peritoneal losses, altered activity, inhibition, decreased intestinal absorption, or drug interactions should be considered and is addressed in [Chapter 26](#), Vitamin Metabolism and Requirements in Chronic Kidney Disease and Kidney Failure.

## Conclusion

PD patients require special attention regarding their food intake. The nutritional derangements that may occur as a result of the patient’s disease states and PD treatment require careful assessment and monitoring of the patient’s nutritional status. Similarly, dietary counseling that can formulate meal plans that meet and take into account the patient’s individual nutritional needs, socioeconomic condition, cultural status, food preferences, and food habits is the key to facilitating dietary adherence. Also, highly important is close follow-up of the patient with frequent visits with a dietitian who is an integral part of the interdisciplinary renal team. With regard to medical nutritional therapy, there is no single rule that fits all patients. Rather, an individualized plan for nutritional assessment, planning the diet, training the patient, and follow-up of the patient is the key to achieving satisfactory results.

## Introduction

Kidney transplantation is a renal replacement therapy for patients with end-stage kidney disease (ESKD) that, when successful, largely corrects the metabolic abnormalities associated uremia and dialysis. However, side effects of immunosuppressive medications and posttransplant changes of lifestyle, together with perceived dietary freedom after successful transplantation, introduce a new set of metabolic challenges [1]. These may lead to clinical problems such as hypertension (HT), diabetes, dyslipidemia, and obesity. Together with preexisting comorbidities, these may negatively impact short- and long-term health outcomes for kidney transplant recipients (KTRs), including delayed graft function (DGF), acute rejection (AR), chronic allograft nephropathy (CAN), and reduced recipient and graft survival [2].

Nutritional challenges begin before kidney transplantation and change overtime after transplantation (Fig. 33.1). Emerging evidence suggests pretransplant nutritional status may affect posttransplantation outcomes, indicating that it is important to maintain optimal nutritional care during maintenance dialysis therapy and in preparation for transplantation. Posttransplant nutritional management is described in the previous chapter on nutritional management of kidney transplantation in the third edition of this book [3], from the evidence-based renal nutrition practice guidelines entitled, the Caring for Australasians with Renal Impairment (CARI) guidelines [4] and National Kidney Foundation Kidney Disease Outcomes Quality Initiative clinical practice guidelines

for nutrition in chronic kidney disease (CKD) [5]. Over the years, additional evidence from observational and interventional studies on various aspects of management have supported the potential benefit of incorporating nutrition in the routine medical care of KTRs.

This chapter begins by reviewing the evidence that pretransplant nutrition is a determinant of posttransplant outcomes. We then review the currently available practice guidelines and new literature on nutrition posttransplantation, covering traditional and new topics such as dietary patterns and nutritional intervention trials, spanning from the acute posttransplant period, through the maintenance phase, and into the period of the failing graft. We conclude with a general, practical approach to the nutritional management of potential and established KTRs.

## Pretransplant factors affecting posttransplant outcomes

### Weight and body mass index

Nutritional abnormalities in KTRs, including those present pretransplant and those that develop after transplantation, may lead to undesirable outcomes that affect the quality of life, complication burden, and graft and patient survival. The World Health Organization (WHO) uses body mass index (BMI in kg/m<sup>2</sup>) classifications to categorize body weight as underweight (<18.5), normal (18.5–24.9), overweight or preobesity (25.0–29.9), obesity class I (30.0–34.9),

## Kidney function

FIGURE 33.1 Schematic diagram showing nutritional and related factors affecting kidney transplant recipients. *BMD*, bone mineral density; *CVD*, Cardiovascular disease; *HT*, hypertension; *NODAT*, new-onset diabetes after transplantation; *PEW*, protein-energy wasting; *TP*, information from kidney transplant specific study.

obesity class II (35.0–39.9), and obesity class III (40 or greater) [6]. In the general population, overweight and obesity are associated with increased morbidity and mortality risk. Therefore public health and WHO messages have always emphasized, in the general population, the importance of attaining a healthy weight. This message is almost certainly relevant to transplant candidates and recipients.

Underweight is a relatively uncommon problem among KTRs. However, registry studies have revealed powerful associations between low BMI and an increased incidence of posttransplant infection and mortality [7,8]. In one large US registry study, being underweight (BMI < 18.5 kg/m<sup>2</sup>, prevalence 3.8%) was associated with late graft failure [adjusted odds ratio (OR), 1.76; 95% confidence interval (CI), 1.16, 2.69; *P* < .01], mainly due to CAN [9]. Obesity is far more common among KTRs, particularly in Western countries. Obesity and the degree of obesity at the time of transplantation have been associated with both poorer early outcomes, including DGF, AR, wound healing disorders and new-onset diabetes, and long-term outcomes, including cardiovascular (CV)

morbidity and mortality [2,7,9–11]. Moreover, weight gain is common after kidney transplantation, averaging about a 10%–20% gain in body weight, that occurs mostly during the first year after renal transplantation [12,13], which further negatively affects outcomes.

An important question is whether the presence of obesity should be taken into account when accepting candidates into the kidney transplant program. To examine the effects of obesity at the time of transplantation on outcomes, several studies compared nonobese (BMI < 30 kg/m<sup>2</sup>) and obese (BMI ≥ 30 kg/m<sup>2</sup>) patients. The studies generally demonstrated inferior graft and patient survival among obese recipients [7,11,14,15]. However, in a larger and more sophisticated USRDS registry analysis, Gill et al. found that obese candidates who received a kidney transplant experienced significantly improved survival as compared to those who remained on the waitlist. A survival benefit was evident for all strata of obesity, including patients with BMI > 40 kg/m<sup>2</sup>, with the exception of African-Americans with BMI > 40 kg/m<sup>2</sup> [16]. It should be emphasized that these findings are

not in conflict with the other reports that outcome is superior in nonobese as compared to obese patients who receive a kidney transplant [7,11,14,15]. In a single Australian transplant center with a rigorous CV disease screening program for transplant candidates, the prevalence of obesity was found to be 12% (59/493) in transplanted patients over a 6-year period of study [11]. The 5-year survival analysis between the nonobese and obese groups did not show any significant difference for graft survival (83% vs 84%,  $P = \text{NS}$ ) or patient survival (91% vs 91%,  $P = \text{NS}$ ). For short-term outcomes, obese patients were more likely to experience superficial wound breakdown (14% vs 4%,  $P < .01$ ) and complete wound dehiscence (3% vs 0%,  $P < .01$ ) and tended to have a higher rate of wound infections (15% vs 8%,  $P = .11$ ). No significant difference between the two groups was shown for operative duration, postoperative complications, hospitalization, DGF (or AR episodes. On multivariate analysis, BMI was found to be an independent risk factor for wound breakdown (OR, 1.21; 95% CI, 1.09–1.34;  $P < .001$ ), but not for other posttransplant complications, hospitalization, graft loss, or patient survival.

With regard to intermediate outcomes, in an analysis of 5684 patients from the Australian and New Zealand Dialysis and Transplant registry, obesity was associated with greater odds for DGF (adjusted OR, 1.56; 95% CI, 1.23–1.97;  $P < .001$ ) and 6-month AR (adjusted OR, 1.25; 95% CI, 1.01–1.54;  $P < .04$ ) [7]. Other results were observed in a center in the United States, with 193 patients with >6 months of follow-up; there was an increased incidence of surgical complications in the obese kidney transplant recipients; however, these individuals did not show an increased rate of AR or graft or patient loss [14]. When comparing the outcomes of morbidly obese KTRs ( $n = 23$ , BMI 37–56 kg/m<sup>2</sup>) with nonobese KTRs ( $n = 244$ , BMI 25 kg/m<sup>2</sup>) at another US transplant center, the morbidly obese KTRs had more complications and a greater length of hospital stay (LOS), but there was no difference in the 3-year graft and patient survival [15].

Thus the current literature demonstrates that the major adverse effect of obesity on kidney transplant outcomes is an increase in wound or surgical complications, but graft function and graft and patient survival are not negatively affected by obesity. These findings suggest that obesity, and even morbid obesity, should not per se preclude access to kidney transplantation. These observations are supported by a systematic review and metaanalysis of 17 studies, including 138,081 patients that found obese patients have similar survival to recipients with normal BMI [hazard ratio (HR), 1.24; 95% CI, 0.90–1.70] [17].

BMI is crude measure of adiposity; for example, greater muscle mass may also increase the BMI. In a

cohort of 10,090 hemodialysis-dependent transplant candidates, patients with healthier body composition, namely, those who had larger pretransplant muscle mass, as indicated by higher pretransplant serum creatinine levels, were found to have greater posttransplant graft and patient survival [18]. Consistent with this finding, the waist-to-hip ratio (WHR) has been reported to be more closely associated with posttransplant complications than the BMI [19].

Traditional research in this area has tended to focus on weight recorded at the time of study and its relationship with defined adverse outcomes. Weight “change” from pre- to posttransplantation has seldom been investigated. A patient’s nutritional status while waiting for transplantation can change, whether it is intentional weight loss in obese patients that is intended to achieve an arbitrary BMI target for enrolling in the transplant program or unintentional loss due to intercurrent illnesses.

In retrospective analyses of 94,465 recipients of deceased donor kidney transplantation (DDKT) [20], the relationship between the weight change from the time of enlistment into the transplant program until transplantation was examined with regard to three outcomes: LOS posttransplant, all-cause graft failure, and mortality. Weight change was categorized into 5% increments: <5% change,  $\geq 5\%$ –<10% weight loss,  $\geq 10\%$  weight loss,  $\geq 5\%$ –<10% weight gain, and  $\geq 10\%$  weight gain. Median follow-up time posttransplant was 5.0 years [interquartile range (IQR), 3.1–7.7 years]. The nonlinear, unadjusted associations between relative pre-DDKT weight loss, longer transplant LOS, higher graft loss, and higher mortality were examined. The median weight change was 0 kg (IQR, –3.5 to +3.9 kg). However, 11% of patients lost >10% of their enlistment weight. Compared to those with <5% weight change pre-DDKT (52% of total studied subjects), these former patients had longer average transplant LOS by 0.66 days (95% CI, 0.23–1.09;  $P = .003$ ), higher graft loss (adjusted HR, 1.11; 95% CI, 1.06–1.17;  $P < .001$ ), and higher mortality (adjusted HR, 1.18; 95% CI, 1.11–1.25;  $P < .001$ ) independent of their BMI or other recipients, donor, and transplant factors. The major limitations of this study were such unmeasured confounders as body composition, inability to identify volitional weight change, and the interactions between comorbid conditions and weight change.

In analyses of 632 transplant-waitlisted hemodialysis patients, mortality was predicted using the 13 week-averaged BMI, the pretransplant serum creatinine as a surrogate of muscle mass, and the changes in these variables overtime [8]. Each kg/m<sup>2</sup> increase in BMI was associated with a death HR of 0.96 (95% CI, 0.95–0.97); the lower 4th and 5th quintile of serum creatinine had an HR of death of 0.75 (95% CI, 0.66–0.86)

and 0.57 (95% CI, 0.49–0.66), respectively. Patients with minimal weight change ( $< \pm 1$  kg) over 6 months had a lower death risk as compared to those whose weight decreased in the range of 3– $< 5$  kg (HR, 1.31; 95% CI, 1.14–1.52) and a weight loss of 5 or more kg (HR, 1.51; 95% CI, 1.30–1.75). This study showed that hemodialysis-dependent transplant candidates with a lower BMI or muscle mass and/or weight or muscle loss have higher mortality. Similar to the previous study, the effect of intentional weight change was not known. It should be remembered that people who ingest large amounts of meat (i.e., striated muscle) or creatine supplements, for example, for physical fitness, can increase their serum creatinine independently of changes in their muscle mass.

Given the rising prevalence of obesity among kidney transplant candidates and potential candidates, coupled with evidence that obesity imparts potential increased risks of short- and long-term posttransplant complications and costs, the pros [21] and cons [22] of pretransplant weight loss have been debated [23]. No clear answer is apparent. The association of pretransplant weight loss with the higher posttransplant mortality noted earlier, coupled with the costs of delaying transplantation to achieve weight loss through diet or other strategies, argue strongly in favor of transplanting patients regardless of their obesity status. Advances in surgery and posttransplant management and new immunosuppressive medications have reduced the risk of posttransplant complications and may render posttransplant strategies to lose weight safer than pretransplant attempts. Current literature is unable to definitively answer this debate.

### Protein-energy wasting/malnutrition

In contrast to overnutrition, the presence of malnutrition, irrespective of body weight or BMI, is predictive of poor posttransplant outcomes. Serum albumin is a surrogate marker of protein-energy wasting (PEW) and inflammation in chronic dialysis patients and can predict poor posttransplant outcomes [24,25]. In a cohort of 8961 hemodialysis patients who underwent their first kidney transplantation, a higher last-3-month averaged pretransplant serum albumin was associated with lower risks of mortality, graft failure, and DGF [26]. For every 0.2 g/dL higher pretransplant serum albumin concentration, there was a 13% lower all-cause mortality (HR, 0.87; 95% CI, 0.82–0.93), 17% lower CV mortality (HR, 0.83; 95% CI, 0.74–0.93), 7% lower combined risk of death or graft failure (HR, 0.93; 95% CI, 0.89–0.97), and 4% lower DGF risk (OR, 0.96; 95% CI, 0.93–0.99). A pretransplant serum albumin level that was in the lower quintile ( $< 3.77$  g/dL) was

associated with worse short- and long-term posttransplant outcomes.

The malnutrition, inflammation, and atherosclerosis (MIA) syndrome is associated with a high mortality rate in dialysis patients [27,28]. In a retrospective study of 1348 adult KTRs [29], the occurrences of posttransplant fatal and nonfatal acute coronary syndromes (ACS) were analyzed in relation to the pretransplant MIA factors: malnutrition (serum albumin, cholesterol and BMI), inflammation (C-reactive protein level), and atherosclerosis (history of CV, cerebrovascular or peripheral vascular disease). Patients with a higher pretransplant MIA score, which indicates more severe protein–energy malnutrition and/or inflammation, showed worse outcomes of ACS ( $P < .001$ ) and composite outcomes of ACS and all-cause mortality ( $P < .001$ ) than those patients with a lower pretransplant MIA score. Compared with the lowest MIA-scoring group, the highest MIA-scoring group had a higher incidence of ACS (HR, 6.12; 95% CI, 1.84–20.32;  $P = .003$ ). The presence of MIA factors pretransplant, is therefore, an independent predictor of posttransplant CV outcomes.

### Glycemic control

As a nutrition-related metabolic disease, diabetes mellitus is associated with poor outcomes in the general, dialysis and transplant populations. Diabetes present before transplantation [30] and diabetes developing after transplantation [31] are both strongly associated with worse posttransplant outcomes, and with increased CV morbidity and mortality, in particular. The importance of glycemic control in those with diabetes is less well known. In a 6-year follow-up study of a cohort of 2872 diabetic dialysis patients who underwent their first kidney transplantation, the dose–response association between pretransplant glycemic control [determined by hemoglobin A1c (HbA1c) levels] and mortality, graft failure, or DGF was examined [32]. HbA1c (%) was measured quarterly or semiannually for each patient. The patient's average values were assigned to one of seven categories separated by 1% increments:  $< 5\%$ ,  $5\%–6\%$ ,  $6\%–< 7\%$  (reference),  $7\%–< 8\%$ ,  $8\%–< 9\%$ ,  $9\%–10\%$ , and  $\geq 10\%$ . An  $\text{HbA1c} \geq 8\%$  was associated with significantly higher all-cause and CV mortality as compared with an  $\text{HbA1c}$  of  $6\%–< 7\%$  (reference). The HR (and 95% CI) for these adverse events for HbA1c categories of  $7\%–< 8\%$ ,  $8\%$  to  $< 9\%$ ,  $9\%–10\%$ , and  $\geq 10\%$  were, respectively, 0.89 (0.59–1.36), 2.06 (1.31–3.24), 1.41 (0.73–2.74), and 3.43 (1.56–7.56). Pretransplant HbA1c levels were not predictive of posttransplant graft failure or DGF. It was speculated

the elevated blood glucose levels before kidney transplantation may have caused a higher rate of posttransplant infections, inflammation, and other complications of diabetes. It is possible that pretransplant hyperglycemia may be a strong predictor of posttransplant hyperglycemia.

## Nutrition screening for transplant candidates

Guidelines regarding nutritional criteria for selection of transplant candidates have mainly focused on obesity and BMI “cutoff” recommendations. While the recommendations for maximal allowable BMI vary, for example,  $\text{BMI} \geq 30 \text{ kg/m}^2$  [33,34],  $\text{BMI} \geq 40 \text{ kg/m}^2$  [35], most authorities agree obesity per se should not preclude a patient from being considered for kidney transplantation. Often an intervention is recommended to cause weight loss to attain a lower BMI. Some guidelines also recommend screening for other related metabolic abnormalities, for example, CV risk and diabetes.

Current evidence indicates that there are strong associations between abnormal nutritional factors, such as body weight (BMI), change of body weight, body composition, optimal glycemic control, PEW or MIA syndrome, and poor short- or long-term posttransplantation outcomes. However, apart from obesity, the current guidelines have not addressed other nutritional characteristics as part of the screening process. In addition to obesity and BMI recommendations, the recent Kidney Disease: Improving Global Outcomes (KDIGO) guidelines include screening for other nutritional matters, which also tend to be obesity- or weight-related, for example, WHR or undernutrition and frailty, and are largely concerned with their relationship to the transplant patient’s postoperative management and healing [36].

## Nutritional management of transplant candidates

The majority of kidney transplant candidates are in a maintenance dialysis program, with uncertain waiting times for transplantation that vary from months to years. The long-term exposures of these patients to nutritional derangements caused by uremia, the dialysis procedures per se, comorbidities, physical inactivity and deconditioning [37], are likely to predispose them to poor posttransplant outcomes. Recent reviews [37] and various clinical guidelines [5,38] have described various aspects of nutritional management for maintenance dialysis patients to improve outcomes, such as treating PEW, improving nutritional status and body composition, weight reduction in obese patients, or serum phosphorous control to manage mineral bone disorders

(see also Chapter 23: Calcium, Phosphate, PTH, Vitamin D and FGF-23 in CKD-Mineral and Bone Disorder; Chapter 24: Phosphate Metabolism and Fibroblast Growth Factor 23 in Chronic Kidney Disease; Chapter 31: Nutritional Management of Maintenance Hemodialysis Patients; Chapter 32: Nutritional Management of Chronic Peritoneal Dialysis Patients; and Chapter 34: Nutritional Management of the Child with Kidney Disease).

Multifaceted and multidisciplinary management of weight reduction for obese transplant candidates [39] may include dietary counseling and behavioral modification, including the use of a very low calorie diet with meal replacement [40,41], exercise training, pharmacological intervention or bariatric surgery (see Chapters 40–42) [42,43]. Bariatric surgery is known to improve glycemic control or “cure” diabetes in many non-CKD patients [44] and may potentially benefit patients on transplant waitlists. While bariatric surgery appears successful in helping patients move onto transplant waitlists, the long-term safety of losing weight pretransplant is uncertain [45]. All such weight loss treatments should be accompanied by structured dietetic monitoring. Interventions that cause severe deficits of energy or nutrients may induce short- or long-term nutritional complications, for example, anemia, osteoporosis, or protein malnutrition [46], and may paradoxically increase the risk of posttransplant mortality. Exercise intervention by itself may or may not induce weight loss, but it will often engender physical and metabolic improvement [47], both of which are beneficial to patients with ESKD (see Chapter 51: Exercise Training for Individuals With Advanced Chronic Kidney Disease). In summary, non-surgical interventions should be encouraged as first-line therapy for kidney transplant candidates, despite the current lack of high-level evidence of their value. The exact indications for bariatric surgery for kidney transplant candidates still need to be established.

## Nutritional considerations for kidney transplant recipients

### What the guidelines say

The posttransplant period is broadly divided into three phases: acute, maintenance, and failing transplant, with the last phase often involved with preparing the patient to return to chronic dialysis. Nutritional challenges change over the life of the kidney transplant patient (Fig. 33.1). Some clinical practice guidelines, such as the CARI [4] and KDOQI [5], provide comprehensive recommendations for nutritional management posttransplantation, whereas the Renal Association guidelines include dietary intervention as part of

lifestyle management [48]. KDIGO [49] and the European Renal Best Practice Guidelines [50] mainly focus on the management of obesity and diabetes, including new-onset diabetes after transplantation (NODAT).

As noted earlier, the chapter on transplant nutrition in the third edition of this book [3] was based on the CARI guidelines [4], which were developed through a rigorous consultation process with professionals from various health-care disciplines who care for KTRs [51]. A total of 13 topics were identified for systematic review of the literature; then the evidence was graded and synthesized to formulate evidence-based recommendations. Precisely, 9 of the 13 topics became the CARI guidelines, and the 4 additional topics on nutritional assessment and medications were listed in the Dietitians Association of Australia nutritional guidelines for adult KTRs [52]. This section will now review and summarize the latest nutritional recommendations on the nine CARI guideline topics, including recommendations from such other evidence-based guidelines as the KDOQI, KDIGO, European and Renal Association (UK) guidelines. We will discuss what is known and what has emerged since the previous guidelines and book chapter were published, with a summary of the latest recommendations.

## Anemia

Anemia is defined as a hemoglobin (Hb) concentration of  $\leq 12$  g/dL in women and  $\leq 13$  g/dL in men. Posttransplantation anemia (PTA) is common both in the early and late posttransplantation periods and is an independent risk factor for CV death, graft failure, and all-cause mortality. PTA is not simply a reflection of low glomerular filtration rate (GFR). Chadban et al. compared a cohort of KTRs with a cohort of community-based people with CKD matched for kidney function and found a 10-fold excess of anemia among the transplant group, a prevalence of 30% versus 3.4% [53]. In another cohort of 1139 KTRs, 36.2% had PTA and 11.7% had severe anemia (Hb  $< 11$  g/dL) [54]. Severe anemia was associated with a reduced composite of patient survival and graft survival during the initial period of time after transplantation ( $< 1251$  days after transplantation: HR, 6.26; 95% CI, 3.74–10.5;  $P < .001$ ). This study also examined the effect of nutritional deficiencies, such as for iron, folic acid and vitamin B<sub>12</sub>, on outcomes. A nonsignificant trend for the association between anemia due to nutritional deficiencies (29.1%) and outcome was observed (HR, 3.07; 95% CI, 0.93–10.17;  $P = .067$ ). The relationship to anemia of nutrition-related factors, such as vitamin B<sub>6</sub>, protein intake protein-energy status, and presence of PEW,

was not examined. Anemia due to acute kidney injury, AR, or infection was also associated with poor outcomes in this early period. Anemia remains highly prevalent and often requires pharmacological treatment with erythropoietin and transfusions. The most identifiable risk factors for PTA are mainly related to clinical morbidity, for example, reduced kidney function, AR, and infection [55].

The majority of guidelines mainly focus on pharmacological management or the use of pharmacological doses of nutrients, for example, iron [56], to manage anemia. There are few or no dietary or nutritional recommendations. Consistent with these guidelines and until more evidence-based data are available, the following recommendations from CARI guidelines on the nutritional management of anemia [57] remain valid:

- No recommendations possible based on Level I or II evidence.

Based on Level III and IV evidence, the suggestion for nutritional care is as follows:

- It is appropriate to use pharmacological doses of nutrients in conjunction with dietary interventions to correct anemia.

## Bone disease

Metabolic bone disease is highly prevalent among patients with ESKD. Immunosuppressive therapy, particularly glucocorticoids, and preexisting hyperparathyroidism may further exacerbate the maladaptive responses of bone-mineral metabolism posttransplant. There exists a complex interrelationship between minerals (calcium, phosphorus), vitamin D, bone-related hormones [parathyroid hormone and fibroblast growth factor-23 (FGF-23)] [58] and other relevant nutritional conditions, including low body weight, undernutrition, immobility, and diabetes mellitus, and these factors contribute to the pathogenesis of bone mineral disorders after transplantation, which include renal osteodystrophy, osteopenia, osteoporosis, and osteonecrosis (see [Chapter 23: Calcium, Phosphate, PTH, Vitamin D and FGF-23 in CKD-Mineral and Bone Disorder](#); [Chapter 24: Phosphate Metabolism and Fibroblast Growth Factor 23 in Chronic Kidney Disease](#); and [Chapter 25: Vitamin D in Kidney Disease](#)). As a result, KTRs are at high risk of bone fractures and vascular calcification.

Currently, most interventional studies and systematic reviews [58,59] address the use of pharmacological doses of calcium, vitamin D or vitamin D analogs with or without calcium, or bisphosphonates. The role of diet per se in preventing and managing bone disease in adult KTRs is often ignored. The majority of clinical

practice guidelines on bone disease in KTRs focus on pharmacological management, including the use of pharmacological doses of nutrients [49,60]. Few if any, of these guidelines make dietary recommendations. Therefore the following recommendations from the CARI guidelines on the nutritional management of bone disease for KTRs [61] are still valid:

- Kidney transplant recipients should be advised to take the vitamin D analog, calcitriol (or another analog) supplement at a dose usually of 0.25–0.50 µg daily. (Level I and II evidence).

Based on Level III and IV evidence, suggestions for nutritional care are as follows:

- A diet containing adequate calcium-rich foods to meet the National Health and Medical Research Council (NHMRC)-recommended daily intake (RDI) for calcium (1000–1300 mg/day) [62].
- The diet should meet the levels of adequate intake for dietary vitamin D that are recommended for the general population, which assume minimal or no Sun exposure [63] to prevent the development of skin cancer.

## Diabetes mellitus

Posttransplant diabetes mellitus (PTDM) encompasses the 10%–30% of KTRs with preexisting diabetes and the additional 10%–40% who develop NODAT. PTDM is associated with increased risks of CV disease and mortality, and, to a lesser extent, graft failure [64]. In a cohort of 1146 adult KTRs, 29.8% of patients experienced impaired fasting hyperglycemia, and 13.4% developed NODAT one year after transplantation [65]. A higher risk of developing NODAT was seen in patients who were older, male, had a higher BMI, higher pretransplantation serum glucose and triglyceride levels, and lower serum high-density lipoprotein level. Hyperglycemia was independently associated with all major CV events, including cardiac, vascular, and stroke (HR, 1.11; 95% CI, 1.11–1.13;  $P < .0001$ ; HR, 1.17, 95% CI, 1.14–1.12;  $P < .0001$ ; and HR, 1.16; 95% CI, 1.12–1.19;  $P = .003$ , respectively). This risk is independent of the presence of CV disease identified before transplantation. A review of randomized controlled trials (RCTs) of diet and/or exercise to achieve weight reduction demonstrated a reduced risk of developing diabetes in the nonrenal populations [66]. Therefore it is reasonable to recommend such interventions to KTRs, with reduced energy diets, moderate-intensity physical activity, and weight control to prevent the development of NODAT. In light of the diabetogenic properties of some immunosuppressive medications and other transplant-related nutritional abnormalities, for example, wound healing and recovery in the acute

posttransplantation phase, bone mineral disorders, and PEW, well-designed prospective intervention studies, considering all these nutritional factors might provide helpful insights into methods for preventing NODAT.

The majority of guidelines mainly focus on pharmacological management of NODAT or diabetes to achieve normoglycemia, for example, “Consider targeting HbA1c 7.0%–7.5%, and avoid targeting HbA1c 6.0%, especially if hypoglycaemic reactions are common” [49] (KDIGO guidelines, Section 15.2.2) and “Post-transplant diabetes should be managed in collaboration with specialists in diabetic medicine” [48] (UK Renal Association guideline 6.3). There are no published studies examining the safety and efficacy of dietary interventions for the prevention and management of diabetes in adult KTRs. Therefore the following recommendation from CARI guidelines on the nutritional management of diabetes mellitus [67] remains valid:

- No recommendations possible based on Level I or II evidence.

Based on Level III and IV evidence, suggestions for nutritional care should be as follows:

- In line with guidelines for the management of type 2 diabetes in the general population.

## Dyslipidemia

Dyslipidemia is common after renal transplantation and occurs in approximately 60% of patients, both early and late in the course of transplantation. Dyslipidemia is positively associated with kidney graft loss, atherosclerotic CV disease, and CV death [68,69]. According to the Adult Treatment Panel III [70] and the KDOQI working group on managing dyslipidemia in CKD patients [71], dyslipidemia is defined as the presence of at least one of the following serum concentrations: total cholesterol  $\geq 200$  mg/dL; low-density lipoprotein (LDL) cholesterol  $\geq 130$  mg/dL; high-density lipoprotein cholesterol  $\leq 40$  mg/dL; or triglycerides  $\geq 150$  mg/dL. Posttransplantation dyslipidemia is not synonymous with nonimmunosuppressant-mediated hyperlipidemia, as seen in other clinical conditions [72]. Other potential causes of posttransplant dyslipidemia are genetic predisposition, higher age, excess intake of carbohydrates or saturated fats, obesity, proteinuria, renal insufficiency, and certain antihypertensive medicines, for example, diuretics, beta-blockers. A number of small randomized interventional studies in KTRs with dyslipidemia have shown the safety and efficacy of lipid-lowering with a Mediterranean diet [73,74] or the American Heart Association Step One Diet [75]. Similar effects were found in a number uncontrolled intervention studies [76,77].

The majority of guidelines focus on pharmacological treatment for lipid-lowering or comprehensive treatment

algorithms with lifestyle management, including some generic nutritional recommendations, for example, healthy eating (less sugar, cholesterol, and saturated fats in the diet), maintaining a healthy body weight and increasing physical activity or exercise [48,50,78]. The new KDOQI guidelines recommend for kidney transplant recipients a healthy dietary pattern: a Mediterranean diet and increased fruit and vegetable intake [5]. CARI guidelines provided more in-depth recommendations based on Level III and IV evidence (see next). Therefore the following recommendation from CARI guidelines on the nutritional management of dyslipidemia is still valid:

- No recommendations possible based on Level I or II evidence.

Based on Level III and IV evidence, suggestions for nutritional care are as follows (*summary*):

- To eat a diet rich in whole grain, low glycemic index, and high-fiber carbohydrates, as well as rich sources of vitamin E and monounsaturated fat.
- To eat a diet in line with lipid management guidelines for the general population, a daily fiber intake of 25 g for females and 30 g for males.
- Weight reduction in overweight or obese KTRs.
- Plant sterols and stanols: include plant foods that are naturally rich in phytosterols as well as 2- to 3-g phytosterol-enriched food products (such as margarine, breakfast cereal, low-fat yoghurt or milk enriched with phytosterols).
- Limit alcohol to no more than two standard drinks on any day for both men and women.

## Food safety

Immunosuppressive and antibacterial drugs are required lifelong by KTRs to maintain their kidney function. This can increase the risk of food-borne illness from bacteria, viruses, fungi, and parasites [79]. Food-borne illnesses, such as listeria, may impose a serious infection risk for a person who is immunocompromised. Diabetes mellitus, cytomegalovirus infection, and high-dose steroids were identified to be independent risk factors for listeriosis [80]. In an observational study of 102 cases of listeriosis in KTRs, the manifestations of the infection included meningitis, bacteremia, and pneumonia, with a reported mortality rate of 26% [81]. While the incidence of food-borne illnesses may appear low, the effects can be devastating. A comprehensive review on food safety for solid organ transplant (SOT) patients describes the mechanisms, clinical consequences, sources of food-borne illnesses, and food safety practices needed to minimize risks [79]. Prevention is the key, starting with “clean”

(handwashing), “separate” (prevent cross-contamination), “cook/chill” (correct time/temperature), and “adequately cook” all animal foods, as well as ensuring safe drinking water. An education program for the patients and their families that involves a dietitian is recommended.

The recommendation from CARI guidelines on the nutritional management of food safety is as follows:

- No recommendations possible based on Level I or II evidence.

Further, there is no Level III or Level IV evidence relevant to food safety. The suggestions for clinical care are based on the available data regarding the incidence and prevalence of food-borne illnesses in this group of patients (*summary*):

- It is prudent to provide general food safety advice to KTRs.
- A consultation with a dietitian is important to identify the most important food safety issues, and
- Dietary modifications relevant to each individual patient, and to ensure dietary requirements are met while food safety precautions are followed.
- The patient should understand that during the early posttransplant period and in periods of acute illness, the likelihood of food-borne infection is high due to significant suppression of the immune system.

Transplant patients are generally motivated by their desire to maintain wellness and personal health and will usually maintain good food safety and hygiene practice in response to credible education information [82]. However, a study examining reported food safety behavior in SOT patients (total = 197, KTRs = 117) found patients often consumed foods that increased their risk of food-borne infections [83]. Within the first year after transplantation, patients reported they followed food safety recommendations rather closely. Although approximately 70% reported they showed concern and sought information on food safety, only 27% recognized all risks of food-borne infection. The incidence of proven food-borne infections was 17.9% 5 years after transplantation (95% CI, 9.9%–30.9%). Most importantly, food-borne infections occurred exclusively among the patients not following food safety recommendations. These results underscore the importance for long-term, ongoing food safety education.

## Hypertension

The prevalence of HT among KTRs ranges between 50% and 80%; it is a risk factor for chronic allograft injury, shortened graft survival, and CV morbidity and mortality [84–86]. The risk factors for posttransplant

HT include organ donor age, allograft dysfunction (rejection, DGF, CAN), renal artery stenosis, retained native kidneys, use of calcineurin inhibitors and glucocorticoids, and recipient characteristics, including male gender, age, presence of diabetes, presence of secondary hyperparathyroidism, excess weight gain, pretransplant HT, and high BMI [87–89]. The blood pressure (BP) target is <130/80 mmHg for adult KTRs, and pharmacological interventions are recommended by most guidelines if this BP level is exceeded [49].

Studies to manage HT in KTRs have focused on pharmacological interventions [89,90]. The use of angiotensin-converting enzyme inhibitors or angiotensin receptor blocker inhibitors, and/or calcium channel blockers has been associated with better BP control, longer graft survival, and specific benefits in patients with diabetes and/or albuminuria [90]. Few studies have examined the effect of dietary intervention on BP lowering, and they consist of a number of small RCTs and uncontrolled interventional studies focusing on traditional nutritional factors that are known to be effective in the general population, such as sodium reduction and other special diets. The role of nutritional status and nutrient intake in the pathogenesis and treatment of HT is discussed in [Chapter 37](#), Nutrition and Blood Pressure.

The effectiveness of sodium restriction to lower BP in the general [91,92] and the nondialyzed CKD [93,94] population has been well studied. A dietitian supervised regimen of a no added salt diet providing 80- to 100-mmol sodium/day with antihypertensive medications in one randomized clinical trial [95] and in one uncontrolled trial [96] both led to a significant lowering of BP.

Elevated serum homocysteine (tHcy) is associated with cardiovascular disease (CVD) risk in ESKD and is common among KTRs (see [Chapter 26](#): Vitamin Metabolism and Requirements in Chronic Kidney Disease and Kidney Failure and [Chapter 37](#): Nutrition and Blood Pressure). The Folic Acid for Vascular Outcome Reduction In Transplantation (FAVORIT) trial was a multicenter double-blind RCT to examine the effects of high versus low doses of B vitamin supplements on lowering serum tHcy levels and reducing a composite of incident or recurrent CVD outcomes [97]. Mean follow-up was 4 years with a sample size of 4110 stable KTRs; the amounts of daily intakes of the high versus low doses of the vitamin supplements were, respectively, folic acid (5 vs 0 mg), pyridoxine HCl (vitamin B<sub>6</sub>) (50 vs 1.4 mg), and vitamin B<sub>12</sub> (1000 vs 2 µg). The multivitamin supplements significantly lowered serum tHcy by  $-4.6 \pm 4.5$  SD µmmol/L with the high dose vs  $-0.2 \pm 5.1$  SD µmmol/L with the low dose (high vs low dose:  $P < .0001$ ). However, the high-dose supplements did not reduce the composite

CVD outcome, all-cause mortality, or allograft failure [98]. According to the latest published reports, there are no direct analyses of the effect of vitamin supplements on BP in KTRs [99,100]. In post hoc analyses the results of the FAVORIT trial supported the reduced mortality benefits of lower blood systolic pressure [99] but found no evidence of a BP threshold effect on the risk of allograft failure or estimated GFR (eGFR) decline [100]. Such confounders as diet and lifestyle factors were not monitored in this trial.

In the nonrenal populations the landmark-controlled feeding studies—the Dietary Approaches to Stop Hypertension (DASH) diet [101] and DASH low-sodium diet [92]—lower BP in the absence of weight loss (see [Chapter 37](#): Nutrition and Blood Pressure). The DASH diet is low in saturated fat ( $\leq 7\%$ ) and total fat, rich in plant-based foods consisting of wholegrain, nuts, fruit, and vegetables and in low-fat dairy products. The DASH diet provides a healthy eating pattern that is rich in nutrients and food components that are beneficial to CV health, for example, potassium, magnesium, calcium, mono- and polyunsaturated fats, vitamin E, dietary fiber, and antioxidants. The DASH low-sodium diet is the same diet but also low in sodium.

At present, there are no controlled interventional studies that examine BP-lowering effects of the DASH diet in KTRs. In a prospective observational study of 632 adult KTRs, baseline dietary data and adherence to the DASH diet were assessed. A validated 177-item food frequency questionnaire was used to calculate the similarity of the participant's usual diet to the actual DASH diet, as indicated by an overall DASH score [102]. After a mean follow-up of 5.3 years, subjects with the highest tertile of DASH score, when compared to the lowest tertile, had a lower risk of both renal function decline (HR, 0.57; 95% CI, 0.33–0.96;  $P = .03$ ) and all-cause mortality (HR, 0.52; 95% CI, 0.32–0.83;  $P = .006$ ). The independent modifiers of the association between the DASH score and these primary endpoints were baseline eGFR and smoking, but not systolic BP. While a significant inverse relationship between the DASH score and BP at baseline was observed in cross-sectional analyses, the ongoing effect of the DASH score on BP alone and outcomes was not known.

The effect of several other nutritional factors on BP in KTRs has also been studied. In a small RCT, all subjects in both study and control groups were encouraged to follow a sodium chloride restricted diet of <3, 6 g/day of fish oil lowered BP significantly more than a control diet providing with 6 g/day of coconut oil [103]. By the end of the study, the low salt, 6 g/day fish oil KTR group required significantly less antihypertensive medication and had significantly higher

glomerular filtration rates and effective renal plasma flows and fewer AR reactions. In a randomized crossover study of KTRs and maintenance dialysis (hemodialysis and peritoneal dialysis) patients, twice-daily doses of 4.5-g L-arginine (9.0 g/day), a precursor of nitric oxide (NO), led to a vasodilatory response and lower BP in both KTRs and dialysis [104]. When the supplementation was ceased, both systolic and diastolic BP increased significantly. However, confounders such as dietary and lifestyle factors were not monitored in these two studies.

In summary, there have been no large-scale studies that have established whether nutritional intervention will prevent, control, or mitigate HT in KTRs. The majority of guidelines focus on pharmacological management of HT. Therefore the following recommendation from CARI guidelines on the nutritional management of HT [105] remains valid:

- No recommendations possible based on Level I or II evidence.

Based on Level III and IV evidence, suggestions for nutritional care are as follows (*summary*):

- Stable hypertensive kidney transplant recipients should be advised to restrict sodium intake to 80–100 mmol/day (Level III evidence).
- Based on studies in the general population kidney transplant recipients should, when overweight or obese, be encouraged and supported to reduce their weight and be encouraged to do at least 30 min of moderate-intensity physical activity on at least 5 days per week.
- Alcohol should be limited to no more than two standard drinks on any day for both men and women. This advice is based on NHMRC guidelines for lifetime health risks associated with daily alcohol consumption by “healthy” men and women [106].

Based on the evidence from the general population and people with mild to moderate CKD, as described in Chapter 37, Nutrition and Blood Pressure, it seems prudent to also advise KTRs to follow the DASH low-sodium and Mediterranean diets, but perhaps with lower dietary protein intakes ( $\sim 0.8$  g protein/kg/day).

## Hypophosphatemia

Hypophosphatemia, defined as a serum phosphorus level  $<0.8$  mmol/L ( $<2.5$  mg/dL), is common in KTRs. It affects 40%–90% of KTRs during the first months after transplant and may persist for up to 10 years in 25%–30% of recipients [107]. There are two major mechanisms for the hypophosphatemia:

(1) reduced intestinal phosphate absorption and (2) high urinary phosphate loss caused by hyperparathyroidism and elevated serum FGF-23, immunosuppressants for example, high doses of steroids and tacrolimus and tubular damage [108–111]. Hypophosphatemia can cause muscle weakness; in the general population, acute cases of severe hypophosphatemia can cause seizures, rhabdomyolysis, respiratory failure, hemolysis, and myocardial depression [112]. In the long term, it may increase osteodystrophy and fracture risk in KTRs [110]. The abovementioned effects are seldom described in the KTR literature [113,114], except in rare cases of acute phosphate nephropathy leading to impaired allograft function [115,116]. Despite such potential detrimental effects, posttransplant hypophosphatemia is associated with better graft and patient survival [117].

The following recommendations from the CARI guidelines on the nutritional management of hypophosphatemia [118] remain applicable:

- No recommendations possible based on Level I or II evidence.

Based on Level III and IV evidence, suggestions for nutritional care are as follows (*summary*):

- Physicians should be aware that phosphate supplementation has the potential to worsen hyperparathyroidism and may mask phosphorus deficiency beyond 3 months posttransplant (Level IV evidence).
- Kidney transplant recipients should be advised to consume phosphate-rich foods as early as possible after transplantation, once good graft function is achieved.
- Supplementation may be considered if hypophosphatemia persists despite an adequate dietary phosphate intake. The serum phosphate level at which supplementation may be considered and the dose of replacement to be given is unclear and clinical judgment is required.

## Overweight and obesity

The presence of, and degree of, overweight and obesity at the time of transplant are associated with increased risk of surgical and wound complications, but not inferior graft and patient survival, as discussed earlier and in a systematic review [119]. After a successful kidney transplant, several factors tend to promote weight gain resulting in overweight (BMI, 25–29.9 kg/m<sup>2</sup>) or obesity (BMI  $\geq 30$  kg/m<sup>2</sup>). There is relief of uremia improving appetite, removal of the dietary restrictions integral to chronic dialysis treatment, the appetite-enhancing effects of corticosteroid use, and, for many KTRs, continuation of a very

sedentary lifestyle. Hence, transplant weight gain and KTRs often gain an amount of body weight equivalent to 10%–35% of their pregain weight. Weight gain mostly occurs during the first year posttransplant [12,120], with women more prone than men to become obese [121] and higher weight gains seen in indigenous populations [122]. Weight gain is often associated with an increase in fat mass rather than muscle mass [123]. For patients who are undernourished pretransplant, some weight gain may be desirable, but undesirable or excess weight gains are associated with poor short- and long-term outcomes [13]. In one cohort study the greatest survival was associated with 10%–19.9% weight gain in the first year and stable weight (0%–4.9% gain) in the second year. Conversely, a weight gain of 20% or greater during the first year and a 10% or greater weight gain in the second year was associated with increased death risk (year 1: HR, 1.78; 95% CI, 1.13–2.81,  $P = .013$ ; year 2: HR, 1.67; 95% CI 1.01–2.76;  $P = .047$ ). Causes of death were CVD, cancer, infections, and other factors. Weight gain 6 months after transplantation resulting in obesity was independently associated with a statistically significant increase in the incidence of posttransplant HT, diabetes mellitus, and ischemic heart disease [124].

A number of interventional studies show improvements in body weight and other health outcomes in overweight and obese KTRs. In a 2-year RCT a structured dietetics intervention with a Mediterranean-style diet resulted in healthier eating habits and a “trend” for weight loss [125]. In this study the mean transplant vintage was approximately 4.3 years at enrollment, and nutritional intervention failed to achieve significant weight loss in these KTRs. Early intervention to prevent undesirable weight gain may be a more effective measure. In a small, nonrandomized prospective interventional trial, the study group had significantly lower mean weight gain than historical controls, who had not received nutritional advice, at 4 months (1.4 vs 7.1 kg;  $P = .01$ ) and at 1 year (5.5 vs 11.8 kg;  $P = .01$ ). These results support early intensive dietary advice and follow-up to control weight gain during the first year posttransplantation [126].

The “**Intensive Nutrition intervention vs standard nutrition care to avoid excess weight gain after kidney Transplantation**” (The INTENT Trial) was an RCT designed to examine the ability of an intensive nutrition and exercise intervention to reduce weight gain 1 year posttransplantation [127]. Counseling sessions were provided by a renal dietitian on four occasions to the standard care group ( $n = 18$ ) and on 12 occasions to the intensive intervention group ( $n = 19$ ). The intensive intervention group also received an exercise plan from an exercise physiologist delivered over three

visits. The primary outcome measure was weight, and secondary outcomes were body composition, biochemistry, physical function, and quality of life. Both the standard and intervention groups had a moderate and similar increase in weight at 1 year  $2.5 \pm 4.0$  SD kg versus  $4.9 \pm 5.9$  kg, respectively (difference between the two groups;  $P = \text{NS.}$ ), and between-group differences in the secondary outcomes were not observed. However, across the entire cohort, all secondary outcomes improved, except for total body fat, fasting blood glucose and HbA1c [128]. The authors concluded that KTRs did not benefit from an intensive nutrition intervention compared with standard care, although study participants did not gain as much weight as expected—as noted earlier, weight gain during the first year posttransplant is commonly  $>10\%$ . The lack of an observed difference may have been due to the “Hawthorne effect,” where studied subjects alter their behavior due to their awareness of being observed. A personal communication with the authors of this study indicated all participants attended the same transplant clinic and shared information, increasing the probability of this explanation. An alternate explanation may be the effectiveness of the “standard care” received in this trial—four dietitian interventions per year. Similarly good outcomes with regard to weight and other parameters, for example, body composition, serum lipid profile, and BP, were observed in an uncontrolled intervention trial in which dietitians provided diet prescription with about four to five consultations during the first year [129]. However, structured nutrition intervention is frequently not available to KTRs, and best practice guideline recommendations are commonly not met due to inadequate dietitian services [130,131]. Many units only practice selective referral for ad hoc interventions for weight reduction after excess weight gain.

In recent years, more attention has been focused on bariatric surgery for weight loss in obese kidney transplant candidates or KTRs (see also [Chapter 41: Bariatric Surgery and Kidney Disease](#)). In one study [132] a cohort of 43 obese pretransplant patients had a median BMI of 43 (IQR 38–48)  $\text{kg}/\text{m}^2$  at the time of their bariatric surgery. At the time of kidney transplantation, their median BMI had decreased to 32 (IQR 28–36)  $\text{kg}/\text{m}^2$ . In the first 5 years (43 months, IQR 20–89) after the transplantation, their median BMI was 33  $\text{kg}/\text{m}^2$ . This reflected a sustained loss of 22% of their body weight. The authors also compared the effects of bariatric surgery performed before and after transplantation, it resulted in a similar maintenance of weight loss (36 vs 32  $\text{kg}/\text{m}^2$ ,  $P = .814$ ) 5 years after kidney transplantation. Compared with matched controls from the national registry, the effect of bariatric surgery on kidney transplantation was associated with a

decreased risk of allograft failure (HR, 0.85; 95% CI, 0.85–0.86;  $P < .001$ ) and mortality (HR, 0.80; 95% CI, 0.79–0.82;  $P < .001$ ). In this study, bariatric surgery before or after transplantation appeared to be a safe and effective approach to weight loss, and improved long-term allograft and patient survival, although other nutritional characteristics of the patients were not noted.

In summary the literature provides only limited evidence to support the beneficial effects and the optimal methods of nutritional intervention to either prevent weight gain or reverse obesity in KTRs. The available data suggest a multifaceted approach to prevent and manage obesity, which includes tailoring immunosuppressants, early structured dietitian intervention, engaging in healthy eating and exercise, and, when indicated, bariatric surgery.

Transplant guidelines note the importance of monitoring obesity [49]. The 2010 CARI guidelines on the nutritional management of overweight and obesity in adult KTRs [133] state the following:

- No recommendations possible based on Level I or II evidence.

The results of the INTENT trial did not add any high level of evidence. Based on Level III and IV evidence, suggestions for nutritional care are as follows (*summary and selective information*):

To prevent excessive weight gain (Level III):

- Kidney transplant recipients should be referred to a dietitian as soon as practicable after transplantation, for written and verbal advice for preventing weight gain.
- Regular follow-up should be arranged to prevent excessive weight gain.

To reduce body weight in overweight or obese kidney transplant recipients (Level IV):

- A diet that is individually planned with a moderate energy restriction of about 30% of energy expenditure should be applied.
- Overweight and obese kidney transplant recipients are more likely to make dietary changes and lose weight with monthly follow-up with a dietitian.

## Dietary protein requirements

The CARI guidelines on protein requirements for KTRs have been widely adopted in clinical practice and intervention studies since they were published in 2010 [134], but, since then, there have been limited metabolic studies on protein and energy requirements for this population. Posttransplant

nutritional considerations can be broadly divided into two periods, the acute and maintenance phases, with the maintenance phase further divided into before and during a later phase of a failing transplant kidney (Fig. 33.1). During the acute posttransplant phase, which comprises the first 4–6 weeks posttransplantation, high doses of immunosuppressants, surgical stress, and wound healing increase the demand for nutrients. Unmet needs may lead to negative nitrogen balance, increased catabolism, and decreased anabolism of body protein that may result in delayed wound healing, loss of muscle mass, and a compromised immune system. A high-protein ( $\sim 1.4$  g/kg per day), high-energy ( $\sim 35$  kcal/kg per day) diet in KTRs is required to maintain neutral or positive nitrogen balance and to limit Cushingoid side effects. Individualized energy prescription is required in the presence of malnutrition, obesity, inflammation, or other adverse events such as sepsis or infection.

KTRs enter the maintenance phase after graft function has stabilized and immunosuppressive medications have been adjusted to maintenance doses. However, optimal levels of protein and energy intake to preserve long-term graft function have yet to be established. To maintain normal nutritional status the current recommendation for optimal protein intake is near the RDI levels (0.75-g protein/kg body weight for females and 0.84-g protein/kg body weight for males) and energy intake is consistent with dietary guidelines for healthy adults (25–35 kcal/kg IBW/d), based on age, gender, level of physical activity, body composition, weight status goals, and concurrent illness or presence of inflammation. These recommendations are also similar to the recommended dietary energy intake for nondialyzed CKD patients [135].

The following recommendation from CARI guidelines on dietary protein requirements [134] remains valid:

- No recommendations possible based on Level I or II evidence.

Suggestions are based on Level III and IV evidence (*summary*) are as follows:

- In the first 4 weeks after transplant a diet providing at least 1.4-g protein/kg body weight may reverse negative nitrogen balance and lead to increased muscle mass in kidney transplant recipients (Level III).
- There is currently no evidence available regarding the long-term protein requirements of stable kidney transplant recipients. Stable kidney transplant recipients on a maintenance immunosuppression regimen, irrespective of renal function, should not exceed the NHMRC Australian Government—RDI of

protein for the general population—0.75 g protein/kg body weight for females and 0.84 g protein/kg body weight for males.

- Regular review by a dietitian is desirable in the long term to ensure that protein requirements are neither exceeded (potentially placing unnecessary pressure on the kidney graft) nor inadequate (possible in periods of AR when prednisone dose may be increased).

### Other nutritional issues

#### Malnutrition

In contrast to common thinking, the dietary freedom and robust appetite due to corticosteroid therapy after kidney transplantation does not always lead to better nutritional status. Suboptimal nutritional status can occur in the acute or maintenance phases after transplantation, especially if the transplanted kidney function decreases to a predialysis stage of CKD (Fig. 33.1). A total of 15%–60% of transplant patients who develop advanced CKD have been found to have malnutrition or PEW [136–138], and a high malnutrition–inflammation score [139]. These conditions predict depressive symptoms [140], anemia [141], and increased risk of mortality [138]. Factors affecting nutritional status of these patients include preexisting undernutrition and comorbidities and treatments that promote increased energy expenditure and requirements and net protein catabolism, such as immunosuppressive medications (e.g., corticosteroids), acute or chronic graft rejection; the uremic syndrome, anorexia, infection, other inflammatory diseases, hospitalizations and hormonal and other metabolic derangements [29,137,142,143].

In summary the prevalence and effects of malnutrition (PEW) in KTRs cannot be underestimated. Therefore sound clinical practice should include careful monitoring of immunosuppressive medications, prevention and treatment of infection and inflammation, and provision of structured nutritional care to prevent or treat malnutrition. Regular nutritional assessment, education, and monitoring are all important practices to improve outcomes.

#### Summary of recommendations for intake of energy and other nutrients

The energy and nutrient requirements, rationales, and recommendations described earlier and in various clinical practice guidelines [4,135] are summarized in Table 33.1.

### Current trends and latest topics of interest

In recent years a “whole food” approach for therapeutic dietary management has gained tremendous recognition. The patient’s microbiome and dietary patterns are two most promising topics that may have potential to improve outcomes in nonrenal and CKD patients, and such approaches may complement the nutritional management of kidney transplant patients. These are described next and summarized in Table 33.2.

#### Gut microbiome

The “microbiome” is a collective term referring to the genetic material within a microbiota, with gut microbiota being “the community of bacteria that reside in the gastrointestinal track.” Gut microbiota influence the nutrition, metabolism, physiology, and immune function of the body. The composition of the gut microbiota is affected primarily by diet; however, drugs, including antibiotics and major health events, such as development of diabetes, kidney disease, and transplant surgery, also play a major role [141,142]. Some compounds that accumulate in kidney failure lead to increased production of potential toxins in the gut. Consumption of “synbiotics” (a combination of prebiotics and probiotics) [144] may be used to modify the gut microbiota. Prebiotics are components of the diet that are selectively utilized by microorganisms to confer health benefits to the host and include inulin and fructo- and galacto-oligosaccharides. Probiotics are live bacteria that are beneficial to health when administered in adequate amounts. Examples include plain yoghurt, cottage cheese, apple cider vinegar, and fermented foods, for example, kimchi and miso [145].

Important determinants of the composition of gut microbiota in CKD are protein, dietary fiber, synbiotics, and bioactive compounds such as polyphenols. Nutritional interventions to modify these food components may modulate gut microbiota to alleviate gut dysbiosis in CKD and hence clinical outcomes [145,146]. In CKD, gut microbiota imbalance or dysbiosis is common and is associated with increased protein-bound uremic toxins, for example, p-cresyl sulfate and indoxyl sulfate, inflammation, and oxidative stress, which are in turn associated with CVDs, morbidity, and mortality [145,147]. A recent comprehensive review discussed the role of the gastrointestinal microbiota in posttransplant associated infections and potential therapeutic options [148]. There is limited evidence for the effectiveness of synbiotic supplementation on reducing uremic toxins [149] or other

TABLE 33.1 Energy and other nutritional requirements after kidney transplantation.

Phase, posttransplant	Immediate or acute	Maintenance
Immunosuppressant dose	High	Maintenance
General comments	Pretransplant diet (usually dialysis diet) until graft functions (see next) Higher protein and energy requirements due to stress of surgery and steroids therapy Strict food safety practice	Healthy and balanced eating as per local dietary guidelines for healthy adults and aligned with DASH and Mediterranean diets (see dietary pattern)
Energy (kcal/kg IBW/d)	30–48 Aim to attain and maintain IBW depending on physical activity level	25–35 Adapted to individual needs to attain healthy weight and optimal nutritional status depending on age, gender, and physical activity levels
Protein (g/kg/d)	1.4	0.75–1.0 (RDI)
Sodium	Usually no restriction in patients with a functional graft May need to increase intake during the polyuric phase	Restricted if HT present, 100 mmol/d or <2.3 g/d (no added salt)
Potassium	Usually no restriction in patients with a functional graft May need to increase intake during polyuric phase	No modifications unless serum potassium is elevated
Calcium (mg/d)	1200–1500	RDI or RDA 1000–1300 according to age group
Phosphorus (mg/d)	~1200 May need phosphate supplementations if serum phosphate is low	No modifications unless serum phosphate is elevated OR when renal function re-entering CKD stages 3–5, to adjust dietary phosphorus intake to maintain serum phosphate levels in the normal range
Other vitamins and minerals	Near RDI or RDA levels	Near RDI or RDA levels
Vitamin and mineral supplementation	Individualized supplementation by nephrologist, for example, iron, phosphate	Individualized supplementation by nephrologist if required
Fluid	A high fluid intake may be needed to maintain balance	Normal intakes

CKD, Chronic kidney disease; DASH, Dietary Approaches to Stop Hypertension; HT, hypertension; RDA, recommended daily allowance of respective countries; RDI, recommended daily intake.

markers and clinical outcomes in CKD [150,151]. These RCTs have been focused on nondialysis CKD and maintenance dialysis patients [150].

In KTRs, infection and rejection complications might result from a liberalized diet after transplantation, as well as from immunosuppressive medications, altered bowel transit time (e.g., postoperative ileus, constipation), or prophylactic and therapeutic antimicrobial agents introducing a new gut microbiota that alters the gut immunomodulation. Gastrointestinal upsets such as diarrhea and urinary tract infections are common posttransplant infections. Potential nutritional interventions therefore include synbiotics from diet or supplements. To date, interventional studies to explore the effects of changing the microbiome in KTRs have not been undertaken [148,150]. In summary, until the results of good clinical trials are available to inform

recommendations, KTRs are encouraged to ingest foods that are high in dietary fiber and that contain prebiotics and probiotics (see Table 33.2).

## Dietary patterns

Food and drinks provide energy and nutrients. Food synergy is an important concept that acknowledges the additive effects of dietary constituents on health [152,153]. Dietary patterns describe the overall diet, foods, food groups and nutrients, their combination and variety, and the frequency and quantity with which they are habitually consumed [154,155]. The characteristics and benefits of individual core food groups on the health of CKD patients have been reviewed extensively [156] to support a food-based approach to nutritional intervention. There is little evidence to support individual nutrients working in isolation to exert significant health benefits, for

TABLE 33.2 Recommended food choices for kidney transplant recipients.

Food <sup>a</sup>	Main nutrient	Important food components				Potential benefits for KTRs
		Dietary fiber	Pre-and probiotics	Antioxidants	Flavonoid/ isoflavones	Deduced from general and CV health, nondialysis CKD studies
Core food groups						
Bread, cereals and grain products Whole meal/whole grain products	CHO (unrefined), PO <sub>4</sub> , VitBs and E	✓	✓	✓		↓ Constipation gut microbiota health Others: ↓ CRP levels (E) ↓ Myocardial infarction risk (E) Low GI: ↑ Insulin sensitivity (I) ↓ Mortality (E)
Fruit Vegetables Variety of seasonal colored vegetables High in prebiotics: starch-resistant High in probiotics: fermented vegetables, for example, sauerkraut, kimchi	Vit A, C, and K Vit A, C, and K, Mg, folate, iron in green leafy veg	✓	✓	✓	✓	Constipation gut microbiota health Others: BP (I) CRP (I) ↓ Inflammation and oxidative stress (E) Acidosis (I) CV and all-cause mortality (E) Low GI: ↑ Insulin sensitivity (I)
Meat and alternatives Includes eggs, plant-based proteins, for example, dried beans, legumes, nuts, and seeds Lean cuts of meat, skinless poultry, fish; vegetarian proteins (unsalted) High in probiotics: miso, tempe, fermented soya beans	Iodine, iron, PO <sub>4</sub> , protein, VitBs and B <sub>12</sub> and zinc Omega-3 fatty acids and VitD (in oily fish) N – 6 fatty acids and Vit E (in nuts)	Plant-based proteins ✓	Plant-based proteins ✓	Plant-based proteins ✓	Plant-based proteins ✓	Low AGE products—altered gut microbiome, which may reduce CV risk Others: Fatty fish: ↓ CV and all-cause mortality (E) ↓ Risk MI, ischemic heart disease, stroke (E) Plant-based protein: ↓ Serum lipids (I) ↓ CRP (I)
Milk/dairy and alternatives Fat-reduced varieties if needing to control weight High in probiotics: yoghurt	Calcium, PO <sub>4</sub> , protein, Vit B <sub>2</sub> , An and D		✓	✓		Limited data in TP Phosphate restoration early after transplant ↑ Muscle and bone density (I)
Fat Mono- or polyunsaturated fats. Limit saturated fats and trans-fats	Essential fatty acids, fat-soluble vitamins			✓	✓	Limited data in TP ↓ Serum lipids (I) ↓ Markers of oxidative stress
Other foods and dietary patterns						
Alcohol Limit: moderate	Alcohol			✓		Limited data in kidney health
Salt/sodium Limit to 80–100 mmol/d, avoid processed and salted foods	Sodium					↓ BP (TP and I)

TABLE 33.2 (Continued)

Food <sup>a</sup>	Main nutrient	Important food components				Potential benefits for KTRs
		Dietary fiber	Pre-and probiotics	Antioxidants	Flavonoid/ isoflavones	Deduced from general and CV health, nondialysis CKD studies
Sugars Limit, or optimal level for energy	CHO (refined)					— —
Healthy dietary patterns Local dietary guidelines plus DASH and Mediterranean-style diets that emphasize plant-based foods, good quality animal protein, low sugar	From all core food groups	✓	✓	✓	✓	Limited data in TP Others: ↓ BP (I) ↑ Serum albumin (I) ↓ Serum lipid (I) ↓ Inflammation (I)

<sup>a</sup>Quantity depending on age, gender and physical activity levels.

AGEs, Advanced glycation end products; BP, blood pressure; CHD, coronary heart disease; CHO, carbohydrates; CKD, chronic kidney disease; CRP, C-reactive protein; CV, cardiovascular; E, epidemiology study; EFV, extracellular fluid volume; GI, Glycaemic Index; I, intervention study; IHD, ischemic heart disease; IS, insulin sensitivity; K, potassium; KTRs, kidney transplant recipients; Mg, magnesium; MI, myocardial infarction; Na, sodium; PO<sub>4</sub>, phosphorous; TP, information from kidney transplant specific study; Vit, vitamin.

example, the FAVORIT trial [98]. The most highly cited studies of the effects of diet patterns on health in the non-renal population are the DASH [101] and Mediterranean [157] diets, which share many common features [158] (see Chapter 37: Nutrition and Blood Pressure). The Mediterranean diet also emphasizes the inclusion of olive oil. Other important dietary patterns align with dietary guidelines of individual countries, which take into account regional cultural eating patterns; examples are guidelines for people in Australia [159], Nordic countries [160], and United States [161]. These dietary patterns not only provide guidelines for healthy eating to meet nutrient requirements, expressed as RDIs or recommended daily allowances, but also to reduce the risk of cancer and other chronic diseases. Some guidelines are also designed for therapeutic intervention, for example, lowering BP [162], improving blood lipid profiles or increasing insulin sensitivity [163]. The common features of these dietary patterns are high consumption of fruit, vegetables, whole grains, legumes, seeds, nuts, fish and dairy products, and low consumption of meat (especially processed meat), sugar, and alcohol.

A number of epidemiological studies have described associations between a healthy dietary pattern and reduced risk of CKD [164], delaying progression and improving survival in nondialysis CKD stages 4–5 [165], as well as reduced mortality [166]. However, studies of the effects of dietary patterns on the health of KTRs have been limited. As discussed earlier in the Hypertension section, adherence to a DASH-style diet is associated with a lower risk of both renal function decline and all-cause mortality [164,167]. In a cohort of 632 KTRs, good adherence to the Mediterranean diet was inversely associated with graft failure (HR, 0.68;

95% CI, 0.50–0.91), kidney function decline (HR, 0.68; 95% CI, 0.55–0.85), and graft loss (HR, 0.74; 95% CI, 0.63–0.88) [168]. The Modification of Diet in Renal Transplantation study [169] is currently underway to examine the effects of a low-fat (<15% energy), unrefined plant-based diet versus the Mediterranean diet (control); the primary outcome measure is serum LDL cholesterol and other secondary measures that are validated risk factors for adverse CV events.

Diet recommendations for the KTRs are frequently inferred from the results of studies in nondialyzed CKD patients, as the maintenance phase of kidney transplantation is often considered to be the “returning to the nondialysis-dependent CKD stage.” However, the medications commonly used in the posttransplant phase, and in particular, immunosuppressants and antibiotics, introduce additional physiological and metabolic challenges to nutritional intervention studies. Whether nutritional interventions that are effective for the general and nondialyzed CKD populations are also effective in KTRs remains uncertain and may be difficult to predict in the absence of clinical trials of KTRs. For example, one epidemiological study in hemodialysis patients found no evidence of benefit for Mediterranean or DASH diets with regard to adverse CV events or total mortality [170]. Food-based dietary recommendations for healthy gut microbiota and dietary patterns for KTRs are summarized in Table 33.2.

## Conclusion

This chapter summarizes the various aspects of nutritional management and dietary recommendations for KTRs, from the pretransplant stage to the acute

and maintenance phases posttransplantation. Over the past decade, there has been an increase in both observational and intervention studies that examine the efficacy and safety of nutritional intervention to improve specific health outcomes for KTRs. However, many questions remain unanswered, and current food-based recommendations and guidelines frequently extrapolate findings from studies in the general population or in CKD patients. The limitations of this approach must be acknowledged, given the complexity of the post-transplantation health environment. Acknowledging these limitations, the authors recommend a combined energy–nutrient prescription that is time-dependent after transplantation as the nutritional needs of KTRs change overtime. Nutrient recommendations should be delivered within the framework of the DASH and Mediterranean-style diets in concert with the local cultural patterns of dietary intake. Ultimately, large-scale RCTs are needed to adequately inform nutritional practice. Until then, evaluation of the implementation of these nutritional guidelines may help to direct and improve clinical practice and patient outcomes.

# Nutritional management of the child with kidney disease

Vimal Chadha<sup>1,2,3</sup> and Bradley A. Warady<sup>1,3</sup>

<sup>1</sup>Department of Pediatrics, School of Medicine, University of Missouri—Kansas City, Kansas City, MO, United States

<sup>2</sup>Acute Kidney Injury, Division of Nephrology, Children's Mercy—Kansas City, Kansas City, MO, United States

<sup>3</sup>Dialysis and Transplantation, Division of Nephrology, Children's Mercy—Kansas City, Kansas City, MO, United States

Protein–energy malnutrition (PEM) is a common problem in children with chronic kidney disease (CKD). While the exact prevalence of PEM in children with CKD is not known, an indirect estimate can be gauged from the prevalence of growth failure in these patients, especially during the first few years of life. While several factors such as metabolic acidosis, calci- triol deficiency, renal osteodystrophy, and most importantly tissue resistance to the actions of growth hormone (GH) and insulin-like growth factor-I (IGF-I) contribute to the impaired skeletal growth of children with CKD, malnutrition plays a critical role. Clinical experience suggests that inadequate nutrition may also contribute to an impaired neurodevelopmental outcome in the youngest patients with renal insufficiency [1–4]. Most importantly, physical manifestations of poor growth, such as short stature and low body mass index (BMI), have been associated with an increased risk of mortality in children with CKD [5].

PEM that occurs because of insufficient nutritional intake or an improper diet results in adaptive responses to a negative energy balance, such as hunger, decreased energy expenditure, and preservation of lean body mass in preference to fat mass. These physiologic responses are usually totally reversed by restoring adequate nutritional intake. However, a maladaptive response to a negative energy balance that is characterized by anorexia, increased energy expenditure, muscle wasting, and relative underutilization of fat is less likely to respond to nutritional support only. This maladaptive response has been termed protein-energy wasting (PEW) and the consensus statement by the International Society of Renal Nutrition and

Metabolism defined it as a state of metabolic and nutritional derangement characterized by decreased body stores of protein and fat [6]. The severe degree of PEW, also referred to as cachexia, has been shown to be the strongest predictor of mortality, especially in the adults and the elderly [7].

Until recently, PEW has been understudied and poorly characterized in children with CKD due to challenges associated with the application of adult-defined PEW criteria to the pediatric population. In adults with CKD the diagnosis of PEW is made based on deranged biochemical parameters, reduced body mass, reduced muscle mass, and decreased dietary protein intake (DPI). In children with CKD, these criteria are confounded by abnormal growth and development. Weight loss, which is an essential component of cachexia in adults, is not an appropriate criterion in children who are growing. Therefore a lack of expected weight gain, presenting as a downward shifting of BMI percentiles, is a more reasonable marker to identify growth failure in children. It should be noted that due to the high prevalence of growth retardation and delayed puberty in children with CKD, BMI should be expressed relative to height age (the age at which the child's height would be at the 50th percentile) instead of chronological age. Abraham et al. assessed the prevalence of PEW in a cohort of children with mild-to-moderate CKD in the Chronic Kidney Disease in Children (CKiD) study by using modified pediatric diagnostic criteria, such as a lack of expected weight gain instead of weight loss and BMI for height age. Based on these criteria, the authors reported a PEW prevalence of 7%–20% [8]. Additionally, when

growth indices such as height standard deviation score (SDS) or height velocity SDS were included in the criteria, the presence of PEW was associated with an increased risk for hospitalization [8]. It is noteworthy, that in patients with PEW, overaggressive nutritional supplementation does not completely reverse the body composition abnormalities, notably muscle wasting, and may lead to relative obesity in patients with cachexia [9]. As a result of its major negative impact on growth, PEW in children with CKD is also termed uremic failure to thrive [10].

While PEM and PEW in children with CKD have been recognized for decades, aggressive nutritional supplementation in these children with nasogastric or gastric tube feeding has also led to an increased prevalence of obesity [11]. Data from the International Pediatric Peritoneal Dialysis Network (IPPN) has revealed that being overweight is emerging as a greater problem than undernutrition among children receiving peritoneal dialysis (PD) in developed countries. The latest report from IPPN reported that the overall prevalence of obesity/overweight was 19.7% in comparison to undernutrition that was 8.9% [12]. While underweight was most prevalent in South and Southeast Asia (20%), Central Europe (16.7%), and Turkey (15.2%), overweight and obesity were most common in the Middle East (40%) and the United States (33%) [12]. In addition, the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) database and other reports have shown an increasing prevalence of obesity in pediatric patients with mild CKD, as well as in those awaiting transplantation [13,14]. Multivariate analysis of BMI SDS has shown a U-shaped association between BMI and the risk of death, with extremes in BMI associated with an increased risk of mortality in children with stage 5

CKD [5,15]. Interestingly, this finding contrasts with the data from adults on maintenance dialysis, in whom increased weight seems to be associated with an improved outcome [16].

Thus the therapeutic goals of optimal nutritional therapy of children with CKD should be to maintain BMI as well as linear growth within the normal range and prevent biochemical derangements. The goal of this chapter is, in turn, to provide the reader a comprehensive review of the many factors that impact the nutritional status of infants, children, and adolescents with CKD or receiving maintenance dialysis and to provide treatment recommendations. Since the last publication of this chapter in 2013, the Pediatric Renal Nutrition Taskforce (PRNT) has published clinical practice recommendations (CPRs) on energy and protein requirements [17], and the dietary management of calcium and phosphate [18], in children with CKD stages 2–5 and on dialysis. Where appropriate, information derived from these recent CPRs will be incorporated into this text.

Etiology of malnutrition

The origin of PEM/PEW in children with CKD is multifactorial (Table 34.1); however, an inadequate dietary intake is considered a major contributing factor, especially in infants [19]. Nausea and vomiting are common in infants and children with CKD, with delayed gastric emptying and gastroesophageal reflux being detected in as many as 73% of patients with CKD [20]. Whereas the etiology of these gastrointestinal abnormalities is unclear, factors such as autonomic dysfunction and the actions of uremic toxins on gastric smooth muscle activity have been implicated [21].

TABLE 34.1 Causes of protein–energy malnutrition in children with chronic kidney disease.

- Inadequate food intake secondary to
  - anorexia
  - altered taste sensation
  - nausea/vomiting
  - emotional distress
  - intercurrent illness
  - unpalatable prescribed diets
  - imposed dietary restriction
  - impaired ability to procure food because of socioeconomic situation
- Chronic inflammatory state
- Catabolic response to superimposed illnesses
- Possible accumulation of endogenously formed uremic toxins and/or the ingestion of exogenous toxins
- Removal of nutrients during dialysis procedure
- Endocrine causes such as
  - resistance to the actions of insulin and IGF-I
  - hyperglucagonemia
  - hyperparathyroidism

IGF-I, Insulin-like growth factor-I.

The taste sensation of patients with CKD is frequently altered and likely also influences the voluntary nutrient intake. Although zinc depletion has been linked to anorexia, and a low dietary intake of zinc and low serum zinc concentrations has been reported in children with decreased taste acuity undergoing maintenance dialysis [22,23], a benefit of supplementation with zinc in terms of improving taste acuity and appetite has not been clearly demonstrated. Serum levels of a small peptide hormone “leptin” have been shown to be elevated in patients with CKD and those undergoing maintenance dialysis. Produced mainly in adipose tissue and primarily cleared by the kidney, it is speculated that hyperleptinemia might also contribute to uremic anorexia and malnutrition [24,25]. Finally, patients with CKD usually receive multiple medications, and drugs such as angiotensin-converting enzyme inhibitors or antihistamines may adversely influence taste perception and, in turn, nutrient intake [26,27].

Adolescents are a unique patient group who appear to be particularly vulnerable to malnutrition due to their poor eating habits. They skip meals, favor fast foods, and, in the presence of imposed dietary restrictions associated with advanced CKD, find it difficult to meet the nutritional requirements of normal pubertal growth and development. The diagnosis/presence of advanced CKD may result in substantial emotional distress in many patients and their families, which may adversely affect nutritional intake as well. Finally, the socioeconomic status of the family might also, on occasion, prevent the patient and family from procuring appropriate food items, so-called food insecurity. Historically, household food insecurity has been assessed by indirect methods, such as food availability, purchasing power, consumption profile, and anthropometric measurements, with the main objective to quantify the number of

individuals experiencing food shortage or even outright hunger. Several tools have been proposed for measuring the perception and/or experience of families suffering from food insecurity. The Core Food Security Measurement and the Household Food Security Survey Module used by the Food and Nutrition services of the US Department of Agriculture form the basis for most of the currently used instruments to detect food insecurity [28].

In contrast to simple PEM, which is caused by decreased intake alone, PEW is defined as a complex metabolic syndrome associated with an underlying chronic illness and characterized by a loss of muscle, with or without the loss of fat. While inadequate intake may contribute to PEW, recent evidence indicates that other factors such as systemic inflammation, endocrine perturbations, and abnormal neuropeptide signaling play important roles in wasting in the context of CKD. Several review articles provide a comprehensive perspective of PEW in children with CKD [9,10,29].

### Assessment of nutritional status

Assessment of the nutritional status of children with CKD requires the evaluation of multiple indices, as there is no single measure that by itself can accurately reflect a patient’s nutritional status. A variety of physical measurements and anthropometric data plotted on appropriate growth charts, along with an evaluation of the dietary intake, are required to provide a complete picture. The recommended frequency of the nutritional evaluation depends on both the age of the child and the severity of CKD (Table 34.2).

TABLE 34.2 Recommended parameters and frequency of nutritional assessment for children with chronic kidney disease (CKD) stages 2–5 and 5D [30].

Measure	Minimum interval in months									
	Age 0– <1 year			Age 1–3 year			Age >3 year			
	CKD 2–3	CKD 4–5	CKD 5D	CKD 2–3	CKD 4–5	CKD 5D	CKD 2	CKD 3	CKD 4–5	CKD 5D
Dietary intake	0.5–3	0.5–3	0.5–2	1–3	1–3	1–3	6–12	6	3–4	3–4
Height or length-for-age percentile or SDS	0.5–1.5	0.5–1.5	0.5–1	1–3	1–2	1	3–6	3–6	1–3	1–3
Height or length velocity-for-age percentile or SDS	0.5–2	0.5–2	0.5–1	1–6	1–3	1–2	6	6	6	6
Estimated dry weight and weight-for-age percentile or SDS	0.5–1.5	0.5–1.5	0.25–1	1–3	1–2	0.5–1	3–6	3–6	1–3	1–3
BMI-for-height-age percentile or SDS	0.5–1.5	0.5–1.5	0.5–1	1–3	1–2	1	3–6	3–6	1–3	1–3
Head circumference-for-age percentile or SDS	0.5–1.5	0.5–1.5	0.5–1	1–3	1–2	1–2	N/A	N/A	N/A	N/A
nPCR	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	1 <sup>a</sup>

<sup>a</sup>Only applies to adolescents receiving HD.

BMI, Body mass index; HD, hemodialysis; N/A, not applicable; nPCR, normalized protein catabolic rate; SDS, standard deviation score.

## Evaluation of nutrient intake

Dietary recall and food intake records kept in a diary are the two most common methods used for estimating nutrient intake [31,32]. The dietary recall (usually obtained for the previous 24 hours) is a simple, rapid method of obtaining a crude assessment of dietary intake. Since it relies on the patient's (or their parents) memory, the responses may not always be valid. However, the advantages to the recall method are that respondents usually will not be able to modify their eating behavior in anticipation of this dietary evaluation, and they do not have to be literate to provide the information. The most important limitation of the 24-hour recall method is its poor ability to capture the day-to-day variability in dietary intake. Children may be even more susceptible to this limitation than adults because they tend to exhibit more day-to-day variability [33]. Therefore it may be useful to obtain three 24-hour recalls (preferably, including one weekend day) to more completely evaluate the food intake pattern. A trained dietitian can obtain useful information from patients by using various models of foods and measuring devices to estimate food portion sizes.

Dietary diaries are prospective written reports of foods eaten during a specified length of time, characteristically 3–4 days, including a weekend day. A food intake diary provides a more reliable estimate of an individual's nutrient intake than do single-day records. The actual number of days chosen to collect food records should depend upon the degree of accuracy needed, the day-to-day variability in the intake of the nutrient being measured, and the cooperation of the patient. Records kept for more than 3 days increase the likelihood of inaccurate reporting because an individual's motivation will typically decrease with an increasing number of days of dietary data collection, especially if the days are consecutive [34].

Food records must be maintained meticulously to maximize the accuracy of the diary. Food intake should be recorded at the time the food is eaten to minimize any reliance on memory. Recording errors can be minimized if proper directions on how to approximate portion sizes and servings of fluid are provided. The dietitian should carefully review the food record with the patient for accuracy and completeness shortly after it is completed. While dietary diaries have been shown to give unbiased estimates of energy intake in normal-weight children younger than 10 years, underreporting is common in adolescents [35,36]. Accordingly, 24-hour recalls may be better suited to adolescents. The intake of calories, macronutrients (carbohydrate, protein, and fat), vitamins, and minerals derived from interviews or diaries is typically calculated using computer-based programs.

The food frequency questionnaire (FFQ), is another widely adopted method used to assess dietary intake [37]. The FFQ contains a number of food items (usually >80) that are typically consumed by the cohort being tested, to which the respondent indicates the frequency of consuming a serving of each item over the prior 28 days. The reported frequency of consuming any particular food item is divided by 28 to obtain a daily consumption frequency. For each item included in the FFQ, a reference value is available for the standard portion size by age, and for the average nutrient and energy level based on a review of several existing databases and references. The specific daily nutrient or caloric intake for a particular food item can then be calculated by the following formula: daily consumption frequency  $\times$  standard portion size  $\times$  average nutritional value. Total energy and all other nutrient levels are determined by summing the values obtained for each individual food item.

## Physical measurements (anthropometry)

The evaluation of anthropometric parameters is a fundamental component of the nutritional assessment in pediatrics and must be accurately measured using calibrated equipment according to standardized techniques and, ideally, by the same person on each occasion [30,38,39]. Recumbent length, height, weight, and head circumference are measured directly, and BMI is calculated as weight (kg) divided by height (m) squared; reference values are available for children older than 2 years of age [40,41]. It is important to note that serial measurements are necessary for the assessment of growth.

Once measured, weight, length/height, head circumference, and BMI should be plotted on the appropriate growth chart, specific for the patient's age and sex. For premature infants the growth parameters should be plotted after correcting for their gestational age until they are 2 years old. In 2000 the center for disease control (CDC) published revised North American growth reference charts for infants and children up to 20 years of age [42], and in 2006 the World Health Organization (WHO) released new growth standards for children from birth to 5 years of age [43]. The WHO growth *standards* are distinguished from the CDC *reference* charts in two important ways. First, the children contributing to the WHO Growth Standards were specifically selected to represent children growing under ideal conditions, that is, they had nonsmoking mothers, were from areas of high socioeconomic status, and received regular pediatric healthcare, including immunizations. In addition, a subset of 882 infants, all breastfed for at least 4 months, provided

longitudinal data for 24 months. Second, the study population was of broad ethnic diversity. In turn, an important observation made was that ethnicity had very little impact on growth, indicating that the growth standards reflect a reasonable expectation for growth regardless of ethnicity; only 3% of the variability in growth within the population could be attributed to country of origin [43].

Because the WHO Growth Standards represent ideal growth and ideal growth should be the goal for children with CKD as well, the WHO Growth Standards should be used as the reference for children from birth to 2 years. Thereafter, the differences between the CDC reference curves and the WHO Growth Standards are minimal. For this reason and because the switch is made from length to height measurement at 2 years, this appears to be a reasonable age to make the transition from the WHO Growth Standards to the CDC reference curves [30]. The growth pattern in several specific disorders such as Trisomy 21 (Down syndrome), Turner syndrome, or Marfan syndrome is altered in such a way that it is noticeably and consistently different than what is expected in the general population. For several specific disorders, sufficient data have been gathered to produce meaningful norms tailored specifically to populations with such conditions. Condition-specific growth charts should be used for these children [44].

In the general population, undernutrition is defined as weight-for-age, height-for-age, and weight-for-height more negative than  $-2.0$  SD from the reference median [45]. It is important to recognize that the weight-for-age SDS is not particularly useful in isolation as weight-for-age will be low in growth-retarded children. Therefore it should be interpreted in the context of the height-for-age SDS. Accordingly, BMI is an accepted and standard method of assessing weight relative to height [46]. However, BMI is not completely independent of either age or height because of age-related changes in body proportions. For this reason, BMI is expressed relative to age in developing children [47], where age functions as a surrogate for both height and maturation. In children with CKD, in whom growth retardation and delayed maturation are common, this approach has limitations. Expressing BMI relative to chronological age in a child with growth and/or maturational delay will result in inappropriate underestimation of his or her BMI compared with peers of similar height and developmental age. To avoid this problem, it may be preferable to express BMI relative to height age (the age at which the child's height would be on the 50th percentile) in children with CKD [48]. This approach ensures that children with CKD are compared with the most appropriate reference group: those of similar height and maturation. However,

caution must be used in applying this approach to children outside the pubertal or peripubertal period, for whom the correlation between height age and maturation is less clear. BMI relative to chronological age may be more logical in some cases, particularly when sexual maturation is complete.

In addition to absolute values, all anthropometric measurements should be expressed in terms of SDS, (also known as  $z$  score). An SDS within two standard deviations of the mean encompasses 95% of healthy children; an SDS greater than  $+2.0$  or more negative than  $-2.0$  is abnormal and mandates further evaluation.

Recumbent length is measured in children up to approximately 2 years of age or in older children who are unable to stand without assistance. Height is measured when the child is able to stand unassisted, usually by 2–3 years of age. As recumbent length overestimates height by an average of 0.7 cm with greater variation likely in taller children, the timing of when the length measurement is changed to height measurement should be noted on the growth chart [49]. In older children who are unable to stand, arm span can be used as a surrogate measure of height, although it may slightly underestimate the standing height [50].

Weight should be measured while the child is nude (young infants) or with very light clothing. Special attention should be devoted to patients with edema or who are undergoing maintenance dialysis, since changes in weight are more reflective of shifts in fluid balance than true weight gain or loss. It is important to determine the patient's "dry weight," which can be challenging as growing children are expected to gain weight. Five parameters are helpful for this estimate: measured weight, presence of edema, blood pressure, laboratory data, and the dietary interview. The mid-week, postdialysis weight is used for evaluation purposes in the hemodialysis (HD) patient, and the weight at a monthly visit (minus dialysis fluid in the peritoneal cavity) is used for the child receiving PD. A careful physical examination should be conducted to look for edema in the periorbital, pedal, and other regions of the body. Hypertension that resolves with dialysis is generally indicative of excess fluid weight. Decreased serum sodium, hemoglobin, and albumin levels may be markers of overhydration. Likewise, a rapid weight gain in the absence of a significant increase in reported energy intake or decrease in physical activity must be critically evaluated before it is assumed to be dry weight gain.

The head circumference should be measured in all children up to 24 months of age (or up to 36 months of age if appropriate centile charts are available) with a firm, nonstretchable tape. The tape is placed just above the supraorbital ridges and over the most prominent

point on the occiput as the maximum head circumference to the nearest 0.1 cm is recorded.

Some of the previously recommended anthropometric measurements such as triceps skinfold thickness (TSF) and midarm circumference (MAC) used to calculate midarm muscle circumference and midarm muscle area were excluded from the 2008 KDOQI Pediatric Nutrition Guidelines [30] as skinfold thickness measurement is extremely operator dependent and lacks precision [51] and in the presence of fluid overload, both MAC and TSF are also likely to be overestimated [48]. However, there is renewed interest in measuring the midupper arm circumference (MUAC) to assess muscle mass, as muscle wasting is recognized as an integral component of PEW. The MUAC is measured to the nearest 0.1 cm using a nonstretchable flexible steel tape to measure the midpoint between the acromion and the olecranon process. While MUAC has the potential to offer a simple, low-resource alternative or supplement to BMI in assessing the nutritional status, no studies on the use of this measure in children with CKD have been published to date.

### Special studies of protein catabolism

Protein equivalent of total nitrogen appearance (PNA), which is sometimes inappropriately referred to as protein catabolic rate (PCR), is a useful tool for the indirect estimation of DPI. It is based on the simple principle that during steady-state conditions, total nitrogen losses are equal to or slightly less than the total nitrogen intake [52]. While the majority of nitrogen losses (approximately 65%) occur as urea excretion in urine and/or dialysate [53], nitrogen is also lost as nonurea nitrogen in creatinine, uric acid, feces, skin, and hair. When scaled to body weight, the nonurea nitrogen excretion in children is more than in adults and likely varies by age as dialysate protein losses (per kg) during PD are highest in the youngest patients [53–56]. Protein loss in urine and/or dialysate is an additional source of nitrogen loss. The total nitrogen losses from the body are represented as total nitrogen appearance (TNA). The PNA can, in turn, be estimated by multiplying the TNA by 6.25 based on the fact that the nitrogen content of protein is relatively constant at 16%. Recognizing the practical difficulties associated with the measurement of all sources of nitrogen loss, in addition to the fact that a portion of these losses (e.g., hair and skin) are small and fixed, several researchers have attempted to derive quantitative relationships between TNA and the easily measurable and most abundant source of nitrogen loss, urea nitrogen [53–57].

As protein requirements are primarily determined from fat-free, edema-free body mass, PNA is usually normalized (nPNA) to some function of body weight.

The usual weight used to nPNA is derived from the urea distribution space ( $V_{\text{urea}}/0.58$ ), as this idealized weight does not include the body fat weight.

Several important limitations of PNA should be recognized with respect to its usage in pediatrics. PNA is known to approximate protein intake only when the patient is in nitrogen equilibrium. However, because of growth, children are in an anabolic state and the PNA will, therefore, typically underestimate the actual DPI. It has also been demonstrated that children treated with recombinant human growth hormone may have a significantly increased DPI without exhibiting greater nitrogen excretion, reflective of an anabolic state [53]. On the other hand, in the catabolic patient, child or adult, PNA will exceed protein intake to the extent that there is net degradation and metabolism of endogenous protein pools to form urea. Therefore PNA can fluctuate from day-to-day and a single measurement of PNA may not reflect the usual protein intake. Additionally, PNA estimates have been found to be inaccurate at extremes of protein intake [58,59].

In patients undergoing maintenance HD, the normalized PCR (nPCR), which is equivalent to nPNA, is measured and it is dependent upon the urea generation rate (G) during the interdialytic period [60]. While the nPCR can be calculated simultaneously during formal  $Kt/V$  estimations by urea kinetic modeling, a simple algebraic formula used in pediatric HD patients [61] has been shown to yield nearly identical nPCR results:

$$\text{nPCR} = 5.43 \times \text{est}G/V_1 + 0.17$$

where  $V_1$  is total body water (in  $L = 0.58 \times \text{postdialysis weight in kg}$ ), and  $\text{est}G$  is calculated as:

$$\text{est}G(\text{mg/min}) = \frac{[(C_2 \times V_2) - (C_1 \times V_1)]}{t}$$

where  $C_1$  and  $V_1$  are postdialysis BUN (mg/dL) and total body water (in  $dL = 5.8 \times \text{postdialysis weight in kg}$ ), respectively, from the previous HD treatment;  $C_2$  and  $V_2$  are predialysis BUN (mg/dL) and total body water (in  $dL = 5.8 \times \text{predialysis weight in kg}$ ), respectively, from the current HD treatment, and  $t$  is time (minutes) from the end of one dialysis treatment to the beginning of the next treatment.

A pediatric study demonstrated that an  $\text{nPCR} < 1 \text{ g/kg per day}$  of protein predicted a sustained weight loss of at least 2% per month for 3 consecutive months in adolescent and young adult-aged patients receiving HD whereas serum albumin levels could not [62]. However, in younger pediatric HD patients, neither nPCR nor serum albumin level was effective in predicting weight loss [62].

It should be noted that the measurement of PNA is difficult in children receiving PD and is not considered

a valid marker of their nutritional status. Therefore it has not been recommended as a standard nutritional assessment parameter by KDOQI [30].

## Other measures

*Serum albumin:* Serum albumin was recommended in the 2000 KDOQI Nutrition Guidelines [63] as a marker of nutritional status because PEM may lead to hypoalbuminemia. Many studies have shown that hypoalbuminemia present at the time of dialysis initiation, as well as during the course of chronic dialysis, is a strong independent predictor of patient morbidity and mortality [64–68]. However, despite its clinical utility, serum albumin levels may be insensitive to short-term changes in nutritional status, do not necessarily correlate with changes in other nutritional parameters, and can be influenced by nonnutritional factors such as infection/inflammation, hydration status, peritoneal or urinary albumin losses, and acidemia [69,70]. Therefore while hypoalbuminemia remains an important component of the general evaluation of patients with CKD, its value as an exclusive marker of nutritional status is questionable.

*Bioelectrical impedance analysis (BIA):* BIA is an attractive, noninvasive, and painless tool that can be used for estimating body composition with minimal operator training. Empiric equations have been developed for predicting extracellular, intracellular, and total body water volumes, as well as body cell mass, fat-free mass, and body fat content. In contrast to BIA that uses a single frequency, bioimpedance spectroscopy measures multiple frequencies for bioimpedance analysis and can provide better estimates of body composition [71,72]. It should be noted, however, that while these techniques allow for an accurate assessment of fat-free mass in healthy children, the estimate of fat-free mass of dialysis patients may be confounded by variations in hydration.

*Dual-energy X-ray absorptiometry (DEXA):* Whole-body DEXA is a reliable, noninvasive method to assess the three main components of body composition: fat mass, fat-free mass, and bone mineral mass/density. The accuracy of DEXA is minimally influenced by the variations in hydration that commonly occur in patients on dialysis. Studies of DEXA in this patient population have demonstrated its superior precision and accuracy when compared to anthropometry, total body potassium counting, creatinine index, and bioelectrical impedance [73,74]. The main limitations to DEXA in pediatrics are its substantial cost and the lack of reliable normal values in children on dialysis.

*Subjective global assessment (SGA):* The SGA, a method of nutritional assessment using clinical

judgment rather than objective measures, has been validated for assessment of the nutritional status of adults with ESKD [75]. An SGA specific for the pediatric population has been validated in children undergoing major surgery [76], but its validity in children with CKD has not been established [77]. Appetite assessment is an integral part of the SGA and has also recently been incorporated into a study of children with CKD. In 879 participants of the CKiD study, a glomerular filtration rate (GFR) of  $<30$  mL/min per  $1.73$  m<sup>2</sup> was associated with a 4.46 greater odds of having a worse appetite than those with a GFR  $>90$  [78]. While appetite was not able to predict changes in height, weight, or BMI z-scores, patients not reporting a very good appetite had more hospitalizations over the next year when compared to those who reported having a very good appetite [78]. Finally, in 2001, the malnutrition–inflammation score (MIS) was introduced as one of the CKD-specific nutritional scoring systems, which incorporates seven components of the original SGA plus BMI, serum albumin level, and total iron-binding capacity or transferrin level. In adult patients receiving HD, the MIS is strongly associated with inflammation, nutritional status, quality of life, and 5-year prospective mortality [79].

*Nutrition-focused physical examination:* The so-called nutritional physical examination involves visual assessment and physical palpation of potential areas of fat or muscle wasting, to assess nutritional status. The presence of pitting edema can help differentiate between measured weight and the child's euvolemic weight. A careful examination of the tongue, skin, teeth, breath, and hair may provide important clues suggestive of nutrient deficiency or excess [80] that can be confirmed by appropriate laboratory testing.

## Nutritional requirements

The nutritional requirements for children with CKD and those undergoing maintenance dialysis are generally based on the published recommended dietary allowances (RDA) for healthy children [81]. However, it is important to recognize that the RDA's are estimates of the average needs of the normal population, are meant to be applied to children as a group, and do not take into account the specific requirements of an individual patient. The American Academy of Pediatrics' Committee on Nutrition states that RDAs cannot be used as a measure of nutritional adequacy in children [82].

The basis for the RDA values varies for different nutrients. While the RDA for energy reflects the average energy intake needed to maintain body weight and activity of well-nourished normal-sized individuals

(with an additional provision for infants and children to ensure normal growth), the RDAs for protein are based on protein nitrogen loss (mean + 2 SD) and are further adjusted to account for poor protein quality and individual variability.

The RDAs for a number of nutrients have been replaced by dietary reference intakes (DRIs) [83]. The DRIs are comprised of a set of four reference values: *estimated average requirement* (EAR), *recommended dietary allowance* (also popularly known as *recommended daily allowance*) (RDA), *adequate intake* (AI), and *tolerable upper intake level* (UL). The EAR is the median usual intake value that is estimated to meet the requirements of half of the healthy individuals in a specific age and gender group, while the other half of individuals are at risk for nutritional deficiency and/or chronic disease. EARs are used to assess the prevalence of nutrient inadequacy in a group of individuals. RDAs are intake levels that, according to the available scientific evidence, meet the nutrient requirement of almost all (>97%) healthy individuals in a specific age and gender group. AI values are used when the scientific evidence is lacking to establish an EAR or an RDA. AIs are derived either from experimental data or are approximated from the observed mean nutrient intakes of apparently healthy people. The UL is the highest level of daily nutrient intake that is likely to pose no risk of adverse health effects in almost all individuals in a specified group. The UL is not intended to be a recommended intake level and the potential risk for adverse effects increases if the intake exceeds the UL.

Because multiple national and international bodies have published slightly different recommended values and have used terms that are not directly comparable, the PRNT decided to take a more pragmatic approach and has recently introduced the novel term suggested dietary intake (SDI), which comprises a range of values [84]. With reference to energy requirements, the lower and upper limits of the SDI fall within the lower and upper values of the previously published works that describe the average energy requirement (daily amount of energy considered sufficient to meet the needs of half the population). The lower and upper limits of the SDI for protein fall within the average amount +2 SD given in the published values [i.e., the daily amount of protein considered sufficient to meet the needs for nearly all (97.5%) of the population] [84].

## Energy requirements

Energy requirements are determined by lean body mass; are modified by growth, current nutritional status, and physical activity; and are influenced by

genetics, ethnicity, and environment. The optimal energy intake from food should maintain normal body mass, promote growth and development, and support the level of physical activity performed by the subject. Recommendations for energy intake come from observational and experimental studies, and more recently from studies using doubly labeled water (DLW) along with a factorial method to address physical activity [85]. The DLW technique is considered the “gold standard” for assessing total energy expenditure (TEE), which includes physical activity energy expenditure (the most variable component of TEE), resting energy expenditure (REE), and the thermic effect of food.

Studies that have investigated the optimal requirements for energy in children with CKD found no difference in the REE (also known as basal metabolic rate) between these children and healthy children, after adjusting for lean body mass [86]. Most studies have reported that a dietary energy intake of around 100% of the estimated energy requirement (EER) in children with CKD resulted in acceptable growth. A large, prospective trial enrolled 65 children aged 2–16 years with an estimated glomerular filtration rate (eGFR) <75 mL/min per 1.73 m<sup>2</sup> and showed that growth was normal with median energy intakes of 94%–98% of EAR at baseline and 85%–94% of EAR at 2 years of follow-up in the 51 subjects who completed the study [87].

To date, energy requirements for children with CKD have been considered to be 100% of the EER for chronological age, with further adjustment to energy intake individualized and based upon response in terms of the rate of weight gain or loss that is individually adjusted for the physical activity level and BMI [83,88] (Tables 34.3 and 34.4). Energy requirements for patients treated with maintenance HD or PD are similar to those of predialysis patients. In children receiving maintenance PD therapy, variable glucose absorption takes place from the dialysis fluid depending on the PD modality, dialysate glucose concentration, and peritoneal membrane solute transport capacity [89]. In a study of 31 children older than 3 years on ambulatory PD therapy, the mean energy intake derived from peritoneal glucose absorption was 9 kcal/kg per day [90]. Since many children who receive chronic PD are underweight, the prescribed energy intake in them should exclude the estimated calorie absorption from the dialysate as failure to do so may compromise the nutritional quality of the diet. However, some children—and particularly infants receiving PD therapy—gain weight at a faster rate than normal despite oral and/or enteral energy intakes that are lower than the average requirements. Reduced physical activity and increased exposure to high dialysate glucose concentrations for fluid removal may be

TABLE 34.3 Equations to estimate energy requirements (EERs) for children at healthy weights.

Age	EER (kcal/d) = total energy expenditure + energy deposition
0–3 months	$EER = [89 \times \text{weight (kg)} - 100] = 175$
4–6 months	$EER = [89 \times \text{weight (kg)} - 100] = 56$
7–12 months	$EER = [89 \times \text{weight (kg)} - 100] = 22$
13–35 months	$EER = [89 \times \text{weight (kg)} - 100] = 20$
3–8 years	
Boys	$EER = 88.5 - 61.9 \times \text{age (year)} + PA \times [26.7 \times \text{weight (kg)} + 903 \times \text{height (m)}] + 20$
Girls	$EER = 135.3 - 30.8 \times \text{age (year)} + PA \times [10 \times \text{weight (kg)} + 934 \times \text{height (m)}] + 20$
9–18 years	
Boys	$EER = 88.5 - 61.9 \times \text{age (year)} + PA \times [26.7 \times \text{weight (kg)} + 903 \times \text{height (m)}] + 25$
Girls	$EER = 135.3 - 30.8 \times \text{age (year)} + PA \times [10 \times \text{weight (kg)} + 934 \times \text{height (m)}] + 25$

explanations; in these cases the calorie contribution from dialysate should be taken into account when estimating energy requirements, especially in the setting of obesity.

Historically, a number of studies have shown that the majority of pediatric patients with CKD exhibit an inadequate dietary energy intake [91–93] in association with worsening kidney function [93]. In a large, prospective study of growth failure in children with CKD, caloric intakes were <80% of the RDA for age in more than one-half of food records obtained [94]. While inadequate voluntary energy intake has been clearly demonstrated in infants with CKD [95,96], energy intakes for older children are generally normal relative to their body size [94]. In contrast to prior publications, the recent assessment of dietary intake in children with CKD from the CKiD study revealed that the median energy consumption levels were higher than the recommended values in all age-groups, implying that at least

half of the kids in each age-group consumed more than the recommended value. While there was a decreased energy consumption with the fall in GFR ( $P = .003$ ), younger children were more likely to exceed the recommended caloric intake than their older counterparts ( $P < .001$ ) [97].

Since energy intake is the principle determinate of growth during infancy, normally a period of very rapid growth, malnutrition has the most marked negative effect on growth in children with congenital disorders leading to CKD and can rapidly lead to the loss of as much as 2 SDS for length [98]. More than half (58.3%) of infants with CKD in the 2008 NAPRTCS report had a height SDS worse than  $-1.88$  (mean for all infants:  $-2.34$ ) [99]. However, maximizing caloric intake has been noted to be particularly effective in improving height velocity only in infants with CKD or receiving dialysis [95,96,98]. As children older than 2 years of age with CKD do not generally experience

catch-up growth [100], the provision of adequate energy intake early in life is crucial. Rizzoni et al. [19] demonstrated that the growth of infants with CKD receiving  $\leq 100\%$  of the RDA averaged 53% (range 10%–72%) of expected, whereas it averaged 97% (range 61%–130%) of expected during periods when the energy intake was  $\geq 100\%$  of the RDA. In a study of 35 children younger than 5 years with CKD stages 4–5, significant weight gain and accelerated linear growth were demonstrated in those starting enteral feeding at  $<2$  years of age, while improved weight gain and maintenance of growth velocity were observed in those starting enteral feeds at age 2–5 years, in each case without exceeding normal energy requirements [95]. If children younger than 3 years with a length (or height) for age  $< -1.88$  SDS fail to achieve expected weight gain and growth when receiving an intake based on chronological age, estimated requirements may be increased by using height age–related recommendations.

While worldwide, undernutrition in children with CKD remains a concern, recent data from the IPPN registry reported a 19.7% prevalence of overweight/obesity (compared with 8.9% underweight) in children at the start of the chronic PD [12]. Overweight/obesity is particularly common in North America with prevalence rates of approximately 60% in 2- to 5-year-old children with ESKD and over 20% in all other age-groups. Multivariate analysis revealed that nasogastric/gastric tube feeds was an independent predictor of overweight/obesity [101]. Ku et al. [102] analyzed data from the US Renal Data System from over 13,000 children ages 2–19 years old with ESKD who initiated dialysis 1995 and 2011 and found that whereas the prevalence of underweight children decreased from 12% to 9%, the prevalence of obesity increased from 14% to 18% during the study period. Accordingly, prevention and treatment of obesity in patients with CKD

is important. Energy requirements for overweight or obese children are lower than normal and can be estimated by using equations specific for children heavier than a healthy weight [83].

### Protein requirements

The usual DPI requirement is based on the nitrogen losses in the urine, stool, hair, and nails, in addition to the extra protein needed for growth [103]. It is important that the required protein intake be accompanied by adequate sources of nonprotein energy (i.e., carbohydrates and fats) as inadequate caloric intake results in the inefficient use of dietary protein as a calorie source, with a resultant increased generation of urea. Thus ensuring that caloric needs are met is an important step in assessing protein requirements and modifying recommended protein intake. It is advised that at least 50% of the total protein intake consist of protein of high biologic value such as the protein from milk, eggs, meat, fish, and poultry. However, more recently, it has been argued that plant-based proteins are not only nutritionally adequate but have other beneficial effects that may favor their use in CKD patients [104].

The 2009 KDOQI Pediatric Nutrition Guidelines recommended maintaining the DPI at 100%–140% of the DRI for ideal body weight in children with CKD stage 3 and at 100%–120% of the DRI in children with CKD stages 4–5 (Table 34.5) [30]. Since the publication of the KDOQI guidelines, there have been no studies that support modifying abovementioned statements. At the same time, the recently published PRNT–CPR [17] suggests that the target protein intake in children with CKD 2–5D should be at the upper end of the recommended intake to promote optimal growth, and the DPI should not be reduced below the lowest end of the recommended range that is considered the minimum safe amount.

TABLE 34.5 Recommended dietary protein intake in children with chronic kidney disease (CKD) stages 3–5 and 5D [30].

Age	DRI (g/kg per day)	Recommended for CKD stage 3 (g/kg per day) (100%–140% DRI)	Recommended for CKD stages 4–5 (g/kg per day) (100%–120% DRI)	Recommended for HD (g/kg per day) <sup>a</sup>	Recommended for PD (g/kg per day) <sup>b</sup>
0–6 months	1.5	1.5–2.1	1.5–1.8	1.6	1.8
7–12 months	1.2	1.2–1.7	1.2–1.5	1.3	1.5
1–3 years	1.05	1.05–1.5	1.05–1.25	1.15	1.3
4–13 years	0.95	0.95–1.35	0.95–1.15	1.05	1.1
14–18 years	0.85	0.85–1.2	0.85–1.05	0.95	1.0

<sup>a</sup>DRI + 0.1 g/kg per day to compensate for dialysis losses.

<sup>b</sup>DRI + 0.15–0.3 g/kg per day depending on patient age to compensate for peritoneal losses.

DRI, Dietary reference intake; HD, hemodialysis; PD, peritoneal dialysis.

As there is a nearly linear relationship between protein and phosphorus intake [105], the consumption of a high-protein diet in patients with CKD is frequently associated with the development of hyperphosphatemia [106]. Conversely, low-protein diets decrease the development of hyperphosphatemia, metabolic acidosis, hyperkalemia, and other electrolyte disorders. However, pediatricians are rightly concerned about the potential for harmful effects of severe dietary protein restriction, particularly as it pertains to the growth of infants and young children with CKD. Two randomized controlled trials have compared low-protein versus normal-protein diets in children with CKD [107,108]. In a study of 24 infants with eGFR <55 mL/min per 1.73 m<sup>2</sup>, a significantly lower SDS for length and height velocity was seen in the group of patients randomized to receive a low-protein formula ( $1.4 \pm 0.3$  g/kg per day) as compared to those who received a DPI of  $2.4 \pm 0.4$  g/kg per day [107]. In the second and largest pediatric trial evaluating protein intake, 191 children (2–18 years) with CKD stages 3–4 were randomized to a reduced DPI of 100% RDA ( $0.8$ – $1.1$  g/kg ideal body weight) or an unrestricted intake (mean DPI—181% RDA). This modest reduction in protein intake, with maintenance of energy intake greater than 80% RDA in both groups, did not adversely affect growth, serum albumin, or the rate of CKD progression within the observation period of 2–3 years. Hence, although there is no evidence for a nephroprotective effect of dietary protein restriction, this study did provide evidence that DPI can be safely restricted to  $0.8$ – $1.1$  g/kg per day in children older than 2 years with CKD [108].

While the spontaneous DPI is reduced in association with CKD progression in a manner similar to that of energy intake, the DPI typically still remains far in excess of the average requirements, ranging from 150% to 200% of the RDA [92,94,108]. The recent assessment of dietary intake from the CKiD study revealed that the median protein intake exceeded the recommended levels in all age-groups, particularly among younger participants [97].

There are situations in which the dietary protein requirements may be increased relative to the general recommendations. This is the case in patients with ongoing proteinuria or during recovery from intercurrent illness, and the recommended intake may be adjusted to height age instead of chronological age if evidence of protein deficiency exists or persists. Modification of protein recommendations may also be necessary in obese children. Obese individuals have a greater percentage of body fat, which is much less metabolically active than lean body mass. Therefore it is believed that basing protein (and energy) requirements of obese individuals on their actual weight may overestimate requirements. Conversely, the use of ideal

body weight as a reference for an obese person does not take into account the increase in body protein needed for structural support of extra fat tissue. Therefore a common practice is to estimate protein requirements of obese individuals based on an “adjusted” weight (i.e., adjusted weight = ideal weight for height + 25%  $\times$  [actual weight – ideal weight]), where 25% represents the percentage of body fat tissue that is metabolically active) rather than their actual body weight [109].

Additionally, the optimal protein intake for pediatric patients on maintenance dialysis (CKD 5D) has not yet been well defined. Reviews of nitrogen-balance studies performed in adult dialysis patients with different protein intakes conclude that HD patients are in neutral nitrogen balance with a protein intake as low as  $0.75$ – $0.87$  g/kg per day, and PD patients with a protein intake of  $0.9$ – $1.0$  g/kg per day [110–114]. A single nitrogen-balance study has been performed in dialyzed children [90]. In 31 pediatric patients receiving automated PD, the investigators observed a positive correlation between nitrogen balance and DPI ( $r = 0.671$ ,  $P = .0001$ ) and total energy intake ( $r = 0.489$ ,  $P = .001$ ) and concluded that the DPI should be at least 144% of RDA, and total energy intake 89% of the RDA, to achieve an estimated nitrogen balance of >50 mg/kg per day. A single randomized prospective study in adults [115] and several trials in children [116–118] have addressed the effect of selectively increasing the amino acid supply in patients on PD therapy. Despite increases in amino acid and DPI, no significant beneficial effects on nutritional status and longitudinal growth were achieved by this intervention in children, whereas the urea concentration frequently increased. These results are compatible with the interpretation that it is not possible to induce tissue anabolism by selectively increasing protein and amino acid ingestion, except in subjects with subnormal baseline protein intake. If more protein is ingested than needed for metabolic purposes, all the excess is oxidized and results in the accumulation of nitrogenous-containing end products.

Although dialyzed children require larger amounts of protein per unit of body weight compared to adults to grow in size and lean body mass, this demand is fully accounted for by the age-adjusted pediatric DRI. Hence, the only additional dietary protein requirement justified by evidence is the replacement of dialytic nitrogen losses. In those on long-term PD therapy, daily peritoneal protein losses decrease with age across childhood from an average of  $0.28$  g/kg in the first year of life to less than  $0.1$  g/kg in adolescents [119]. Peritoneal amino acid losses add approximately one-third to the nitrogen lost with protein, resulting in a total additional dietary protein requirement ranging from  $0.15$  to  $0.35$  g/kg, depending on patient age

(Table 34.5). Patients with high-peritoneal transport characteristics tend to have low serum albumin levels, likely due to increased peritoneal protein losses; these patients may have slightly greater protein requirements. Because dialytic protein concentrations can be measured easily, consideration should be given on occasion to monitoring of peritoneal protein excretion and individual adaptation of the dietary protein prescription according to actual peritoneal losses.

Amino acid and protein losses during HD vary according to dialyzer membrane characteristics and reuse. Whereas losses have not been quantified in children, an average of 8–10 g of amino acids and less than 1–3 g of protein are lost per HD session in adults [120–122]. On the basis of three HD sessions per week for a 70-kg adult, this equates to 0.08 g/kg per day. Assuming that dialytic amino acid losses are linearly related to urea kinetics, children can be expected to have similar or slightly higher amino acid losses than adults and an added DPI of 0.1 g/kg per day should be appropriate to compensate for pediatric HD losses.

Finally, there is some concern that a high DPI may prove to be harmful when consumed by dialyzed children. In a DXA study of body composition in 20 children on long-term PD therapy with a mean DPI of 144% RDA, protein intake inversely correlated with bone mineral density, bone mineral content, fat-free mass, and plasma bicarbonate level, suggesting that a high protein intake may cause tissue catabolism and bone loss by worsening metabolic acidosis [123]. However, the most convincing argument for limiting DPI in dialyzed children is derived from the solid evidence supporting the key etiologic role that dietary phosphorus load has in the pathogenesis of dialysis-associated calcifying arteriopathy. As noted previously, there is a nearly linear relationship between protein and phosphorus intake [105], which results in the frequent association between high quantities of protein in the diet and hyperphosphatemia [124]. Hence, it appears most appropriate to limit DPI in children on dialysis to the safe levels known to ensure adequate growth and nutrition in healthy children. Additionally, the DPI may be adjusted to the lower end of recommended intake in patients with persistently high blood urea levels after other causes for high urea levels have been excluded.

## Lipid requirements

Dyslipidemia is a frequently recognized complication of CKD in children [125,126], occurs relatively early in the course of CKD (i.e., stage 3 CKD), and increases in prevalence with decreasing kidney function [126–128]. Baseline data from the CKiD study

reported the presence of dyslipidemia in 44% of 250 children with mild-to-moderate CKD; the most common abnormality was hypertriglyceridemia in 75% [129]. More recently, the CKiD study has reported the change in dyslipidemia with declining GFR and increasing proteinuria in 508 children (76% nonglomerular CKD, 24% glomerular CKD) [126]. The study showed that 35% of patients with nonglomerular CKD had dyslipidemia at baseline that increased significantly over time, while 43% of children with glomerular CKD had dyslipidemia at baseline that remained persistent over time. Declining GFR and worsening proteinuria were independently associated with worsening dyslipidemia [126]. The dyslipidemia seen in children with CKD has complex underlying metabolic alterations and is characterized by increased levels of serum triglycerides in combination with high levels of very-low-density lipoprotein (LDL) and intermediate-density lipoproteins, low levels of HDL particles, and normal or modestly increased levels of total and LDL cholesterol [125,128,130]. This pattern of dyslipidemia has been labeled “atherogenic.” In addition, hypertriglyceridemia has been shown to be an independent contributor to the development of CVD [131,132] and may also accelerate the progression of CKD [133].

While there is no direct evidence indicating that the measurement of lipid status will improve clinical outcomes, the 2013 KDIGO CPG for lipid management in CKD recommends obtaining a lipid profile (total, LDL, HDL cholesterol, and triglycerides) in all children with newly diagnosed CKD (including those receiving dialysis or with a kidney transplant), with annual follow-up measurements [134]. The optimal management of dyslipidemia in children with CKD is not clearly defined. Treatment of malnutrition related to impaired kidney function is essential and should supersede any potential rise in lipid levels that might result from it. On the contrary, prevention and treatment of obesity in patients with CKD is an important strategy to reduce the risk of hyperlipidemia [135]. Correction of metabolic acidosis, vitamin D therapy, and correction of anemia with erythropoietin each also seem to have some normalizing effect on dyslipidemia in children with CKD [136–138]. The KDOQI Dyslipidemia Guidelines’ recommendations [139], endorsed by the KDOQI Cardiovascular Guidelines [140] recommend that the dietary and lifestyle recommendations made for adults are also appropriate for postpubertal children and adolescents with CKD. Therapy with statins or statin/ezetimibe combination is not recommended for children with CKD (including those receiving dialysis or with kidney transplant) who are less than 18 years of age [134]. In 1992 the National Cholesterol Education Program Pediatric Panel Report [141] provided dietary recommendations for all children. These

guidelines were later endorsed by the Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents [142]. The latter publication recommends that in children with identified hypercholesterolemia, less than 25%–30% of calories should come from dietary fat, of which  $\leq 7\%$  should be from saturated fatty acids; the daily cholesterol intake should be  $<200$  mg. For serum triglyceride  $>150$  mg/dL, therapeutic lifestyle changes are recommended along with a low-fat diet and a low intake of simple carbohydrates [134]. The child should be encouraged to ingest complex carbohydrates in lieu of simple sugars and concentrated sweets and to use unsaturated fats such as oils and margarines from corn, safflower, and soy. Plant stanol esters in the form of dietary supplements reduce intestinal cholesterol absorption and may provide a safe and effective means of reducing serum cholesterol.

High intakes of  $n-3$  polyunsaturated fatty acids [omega-3 fatty acids ( $n-3$  FA), docosahexaenoic acid (DHA), and eicosapentaenoic acid (EPA)] have been associated with decreasing TG levels and a decreased risk of heart disease [143,144]. Therefore EPA and DHA, found almost exclusively in fish and marine sources, must be provided in the diet; the best sources are fatty fish (e.g., tuna, mackerel, trout, salmon, herring, sardines, and anchovies) [145]. Although  $n-3$  FAs have been found to be extremely safe by both Health Canada and the US Food and Drug Administration, there is insufficient evidence at this time to recommend routine use of  $n-3$  FAs to treat hypertriglyceridemia in children with CKD.

Dietary fiber, particularly naturally occurring viscous fiber, reduces total and LDL cholesterol levels and high intakes have been associated with reduced rates of CVD. The AI for total fiber is based on daily caloric intake and is 14 g/1000 kcal per day for all children 1 year and older. Dietary fiber is found in most fruits, vegetables, legumes, and whole grains, which are foods restricted in low-potassium and low-phosphorus diets; therefore meeting normal daily fiber

recommendations is challenging for children with CKD. Tasteless mineral- and electrolyte-free powdered forms of fiber (e.g., Unifiber, Benefiber) are available to add to meals or drinks if children are unable to meet their fiber intake by diet. High-fiber diets require additional fluid intake, which may not be possible for oliguric or anuric patients with a strict fluid restriction.

## Bone mineral metabolism

Optimal control of bone and mineral homeostasis is essential, not only for the prevention of debilitating skeletal complications and the achievement of adequate growth, but also for the prevention of vascular calcification and cardiovascular disease. Complications of mineral bone disease (MBD) are, however, common and contribute to the high morbidity and mortality seen in children with CKD. The provision of adequate but not excessive amounts of calcium and phosphorus is thus an important part of CKD management.

## Calcium

Adequate dietary calcium intake during childhood is necessary for skeletal development and acquisition of optimal peak bone mass [146]. The current recommendation is that patients with CKD should achieve a calcium intake of 100% of the DRI, just as their healthy peers (Table 34.6) [147]. While there are no studies to set a safe upper limit of calcium intake for healthy children, KDOQI suggested that 200% of the DRI is the safe upper limit for patients with CKD, as excess calcium is potentially detrimental and can lead to ectopic calcification [148]. Similarly, and in response to the epidemiological evidence linking higher calcium concentrations to increased mortality in adults with CKD, the 2017 KDIGO CPG update for the diagnosis, evaluation, prevention, and treatment of CKD-MBD suggests to avoid hypercalcemia in adult patients with CKD G3a-G5D [149]. In the

TABLE 34.6 Recommended calcium intake for children with chronic kidney disease (CKD) stages 2–5 and 5D [30].

Age	DRI	Upper limit (for healthy children)	Upper limit for CKD stages 2–5, 5D (dietary + phosphate binders <sup>a</sup> )
0–6 months	210	ND	$\leq 420$
7–12 months	270	ND	$\leq 540$
1–3 years	500	2500	$\leq 1000$
4–8 years	800	2500	$\leq 1600$
9–18 years	1,300	2500	$\leq 2500$

<sup>a</sup>Determined as 200% of the DRI, to a maximum of 2500 mg elemental calcium.

DRI, Dietary reference intake; ND, not determined.

case of children with CKD, the Work Group suggested maintaining the serum calcium level in the age-appropriate normal range to meet the higher calcium requirements of the growing skeleton [149].

The main dietary sources of calcium for children are milk, milk products, breast milk, and manufactured infant formulas. Infants and young children usually meet the DRI for calcium with the consumption of adequate volumes of breast milk/infant formula. All standard and most specialized infant milk formulas have a higher concentration of calcium compared to human milk, but lower than cow's milk or the formulas intended for older children. Formulas designed for infants must comply with set compositional criteria, providing a minimum amount of 50–60 mg of calcium per 100 cal and a Ca:P ratio between 1.1 and 2.0 [150,151]. The calcium content of reduced-fat dairy products is comparable to whole milk-derived products. The “milk and milk products” food group (milk, cheese, yogurt, cream, and ice cream) contribute 44%–70% of dietary calcium intake, being highest in the younger age-groups. “Cereal and cereal products” (grains made into pasta, rice, breads, breakfast cereals, and biscuits) contribute 16%–28% of average daily calcium intake. Other sources of calcium, including vegetables, fish, meat, fruit, and confectionary, each contribute between 1% and 7% of daily calcium intake [18]. The variations in foods eaten in different countries or cultures may alter the relative calcium intake from specific food groups [18].

Most problematic is the fact that the largest sources of dietary calcium for most persons are dairy products that are also rich in phosphorus; in turn, phosphorus restriction in the patient with CKD universally leads to a decreased calcium intake. In these situations, calcium supplementation may be required as low phosphorus-, high calcium-containing foods such as collards, dandelion greens, kale, rhubarb, and spinach usually do not make up a substantial part of a child's diet. Several products fortified with calcium such as fruit juices and breakfast foods are commercially available, and limited studies have suggested that the bioavailability of calcium from these products is at least comparable to that of milk [152]. Calcium can also be supplemented in medicinal forms such as carbonate (40% elemental calcium), acetate (25% elemental calcium), and gluconate (9% elemental calcium) salts of calcium that are commonly used as phosphate binders. When used for calcium supplementation alone, ingesting these products between meals maximizes calcium absorption. Chloride and citrate salts of calcium should be avoided as the former may lead to acidosis in patients with CKD and the latter may enhance aluminum absorption.

The absorption of calcium from foods and medications (calcium-based phosphate binders and calcium

supplements) is about 30% but varies between 5% and 82% depending on the food source and vitamin D status of the person. Milk, dairy products, and fortified food have a calcium bioavailability between 30% and 40%, whereas it is below 10% for vegetables and fruits (such as spinach and rhubarb). The calcium intake from phosphorus binders can contribute significantly to dietary calcium intake and should be included when calculating total daily calcium intake in CKD patients.

Excessive calcium intake in conjunction with activated vitamin D analogs can lead to (1) hypercalcemia, (2) adynamic bone disease, and (3) systemic calcification. Therefore the total calcium intake from diet and medications (including phosphate binders) should be within the DRI, and no more than twice the DRI, unless there are exceptional circumstances such as in infants with mineral-depleted bones. Accordingly, the KDOQI guidelines recommend that the combined elemental calcium intake from nutritional sources and phosphate binders should not exceed two times the DRI for age, except for ages 9–18 years (both genders) where two times the DRI (2600 mg) exceeds the UL of 2500 mg (Table 34.6) [30,147,148]. The serum level of total corrected calcium should be maintained within the normal range (8.8–9.5 mg/dL), preferably toward the lower end and definitely not more than 10.2 mg/dL.

The calcium balance in patients undergoing maintenance dialysis is also affected by the dialysate calcium concentration. The calcium balance during PD is usually negative with the use of a dialysate calcium concentration of 2.5 mEq/L and positive with a dialysate concentration of 3.0–3.5 mEq/L [153]. As a result, it may be wise to use a low calcium dialysate (2.5 mEq/L) in children undergoing dialysis who are receiving calcium-containing phosphate binders along with activated vitamin D sterols. On the contrary, a 3.0- to 3.5-mEq/L calcium dialysate should be used if hypocalcemia is present in a child with elevated parathyroid hormone (PTH) (>300 pg/mL) as part of the treatment of secondary hyperparathyroidism (SHPT) and may be needed in children restricted to noncalcium-containing phosphate binders only.

## Phosphorus

In an effort to prevent/control CKD-associated MBD and CVD, serum phosphorus concentrations above the normal reference range for age (Table 34.7) should be avoided in patients with advanced CKD. However, even during the earlier stages of CKD when the serum phosphorus levels are typically within the normal range, the dietary phosphorus load is an

TABLE 34.7 Age-specific normal ranges of blood ionized calcium, total calcium, and phosphorus.

Age	Ionized calcium (mmol/L)	Calcium (mg/dL)	Phosphorus (mg/dL)
0–5 months	1.22–1.40	8.7–11.3	5.2–8.4
6–12 months	1.20–1.40	8.7–11.0	5.0–7.8
1–5 years	1.22–1.32	9.4–10.8	4.5–6.5
6–12 years	1.15–1.32	9.4–10.3	3.6–5.8
13–20 years	1.12–1.30	8.8–10.2	2.3–4.5

Conversion factor for calcium and ionized calcium:  $\text{mg/dL} \times 0.25 = \text{mmol/L}$ . Conversion factor for phosphorus:  $\text{mg/dL} \times 0.323 = \text{mmol/L}$ .

important determinant of the severity of hyperparathyroidism. Dietary phosphorus restriction decreases PTH levels and increases  $1,25(\text{OH})_2\text{D}$ , whereas a dietary phosphorus intake approximately twice the DRI for age aggravates hyperparathyroidism despite little or no change in the serum phosphorus level (the result of elevated FGF-23 levels and enhanced phosphorus excretion) [154]. It is important to note that the higher physiological serum concentrations of calcium and phosphorus that are observed in healthy infants and young children presumably reflect the increased requirements for these minerals by the rapidly growing skeleton. Rickets due to phosphorus deficiency can occur in preterm infants whose diet provides insufficient quantities of phosphorus, as well as in infants and children with hypophosphatemia due to inherited disorders of renal phosphate transport. Hence, when dietary phosphorus is restricted to control hyperphosphatemia and SHPT in children with CKD, subnormal serum phosphorus values are equally important to avoid.

Data from the United States for all age-groups indicate that the highest contributors to phosphorus intake are milk, meat, and grains [155,156]. As with calcium intake, the highest percentage of dietary phosphorus comes from “milk and milk products” particularly in the younger age-groups, while “meat and meat products” account for 15%–20% of phosphorus intake, being highest in older children. Breast milk is relatively low in phosphate, having a concentration about one-half of most standard whey-based formulas and one-third of casein-based infant formulas. For standard infant formulas, only the minimum level (25–30 mg per 100 cal), but not the maximum level of phosphate is regulated [150,151]. Phosphate additives, such as phosphoric acid and sodium phosphate, are used by the food industry to improve the texture, taste, appearance, and shelf life of many processed foods and their presence, but not quantity, is usually indicated on the ingredient list [157]. It is important to note that the phosphorus additive is in the inorganic form that is readily absorbed, in contrast to the organic

form of phosphorus present in natural food, and can significantly increase phosphorus intake. In addition, inorganic phosphates are added to several medications, such as antacids and many antihypertensive medications, as an excipient that aids in dispersion of the active drug ingredient once ingested [158]. The phosphorus load from medications can make a meaningful contribution to the daily phosphorus intake and, thus, should be reviewed carefully with members of the health-care team.

The absorption of phosphorus from food depends on whether it is in an organic or inorganic form. Meats, fish, dairy, vegetables, grains, and nuts contain organic carbon-bound phosphorus, with a bioavailability between 30% and 70%. Plant-based organic phosphorus (including seeds and legumes) is stored in the form of phytate or phytic acid, which cannot be broken down by humans, reducing the bioavailability to 30%–40%. However, as noted earlier, the bioavailability of inorganic phosphorus salts added to processed foods can be as high as 100% [18,157].

Current recommendations suggest that in children with CKD whose serum PTH concentration exceeds the target range but whose serum phosphorus concentration remains normal, the dietary phosphorus intake should be restricted to 100% of the DRI; in contrast, the intake should be restricted to 80% of the DRI when the serum phosphorus concentration exceeds the normal reference range for age (Tables 34.7 and 34.8) [88,148].

Despite the need to restrict dietary phosphorus, most clinicians recognize that an overly restrictive dietary phosphorus intake is not only often impractical, but it can be ill-advised as it may lead to an inadvertent poor DPI [60]. In addition, extremely low-phosphorus diets are typically unpalatable. Young infants are characteristically managed with a low phosphorus-containing milk formula such as Similac PM 60/40 (Abbott Nutrition), Renastart, (VitaFlo Nutrition), Renalcal (Nestle Health Sciences), or by pretreatment of breast milk, infant formula, and cow's milk with sevelamer carbonate (Renvela; Sanofi US) that can effectively reduce the phosphorus content in the supernatant by 80%–90%

TABLE 34.8 Recommended maximum oral and/or enteral phosphorus (mg/d) intake for children with chronic kidney disease (CKD).

Age	DRI (mg/d)	High PTH and normal phosphorus <sup>a</sup>	High PTH and high phosphorus <sup>b</sup>
0–6 months	100	≤ 100	≤ 80
7–12 months	275	≤ 275	≤ 220
1–3 years	460	≤ 460	≤ 370
4–8 years	500	≤ 500	≤ 400
9–18 years	1250	≤ 1250	≤ 1000

TABLE 34.9 Recommended supplementation for vitamin D deficiency/insufficiency in children with chronic kidney disease (CKD) [148].

Serum 25(OH)D (ng/mL)	Definition	Ergocalciferol (vitamin D2) or cholecalciferol (vitamin D3) dosing	Duration (months)
<5	Severe vitamin D deficiency	8000 IU/d orally or enterally × 4 wk or (50,000 IU/wk × 4 wk); then 4000 IU/d or (50,000 IU twice per mo for 2 mo) × 2 mo	3
5–15	Mild vitamin D deficiency	4000 IU/d orally or enterally × 12 wk or (50,000 IU every other wk, for 12 wk)	3
16–30	Vitamin D insufficiency	2000 IU daily or (50,000 IU every 4 wk)	3

[159,160]. It is important to note that some infants may require phosphorus supplementation in the form of sodium phosphate (Neutra-Phos) because of their higher physiological needs, as mentioned previously. Most other patients with CKD require oral intestinal phosphate binders to control hyperphosphatemia. Phosphorus control can be difficult in vegetarians since for the same total quantity of dietary protein delivered, the phosphorus content is greater in protein derived from vegetable sources (average 20 mg of phosphorus per g of protein) versus animal protein (average 11 mg of phosphorus per g of protein). However, the bioavailability of phosphorus from plant-derived food is very low; therefore despite their higher specific phosphorus content, some plant sources of protein may actually result in a lower rate of phosphorus uptake per mass of protein than meat-based foods [30]. Whereas food labels rarely state the phosphorus content [157], chocolates, nuts, dried beans, and cola soft drinks are rich in phosphorus and should be avoided; nondairy creamers and certain frozen nondairy desserts may be used in place of milk and ice cream.

## Vitamin D

Vitamin D plays an important role in the management of CKD-MBD and its deficiency is a risk factor for SHPT

and decreased serum 1,25 (OH)<sub>2</sub>D levels. Ali et al. reported a 20%–75% prevalence of vitamin D deficiency (25(OH)<sub>2</sub>D < 15 ng/mL) in children with CKD stages 1–5, with higher prevalence rates in Hispanics and African-Americans, likely due to increased melanin content in their skin [161]. The CKiD cohort study observed vitamin D deficiency (<20 ng/mL) in 28% of the 506 children at enrollment [162]. Those with 25(OH)<sub>2</sub>D deficiency were more likely to be of nonwhite race, older with higher BMI z-scores, lower milk intake, not receiving vitamin D supplement, had more proteinuria and had higher FGF-23 levels [162]. While the total 25(OH)<sub>2</sub>D and vitamin D-binding protein levels are lower in healthy black adults and black children when compared to white individuals, the bioavailable 25(OH)D levels are not different from white racial groups [163,164]. Current guidelines suggest checking serum 25(OH)<sub>2</sub>D levels once every 6–12 months in children with CKD stages 2–5 [30,165]. If the serum level of 25(OH)<sub>2</sub>D is <30 ng/mL, supplementation with vitamin D<sub>2</sub> (ergocalciferol) or vitamin D<sub>3</sub> (cholecalciferol) is suggested, with the specific dosing regimen dependent on the severity of the deficiency (Table 34.9). Cholecalciferol appears to have higher bioefficacy than ergocalciferol, although long-term comparative trials are lacking in humans [166,167]. During the repletion phase, serum levels of calcium and phosphorus should be measured 1 month following the

initiation or a change in the dose of vitamin D and at least every 3 months thereafter. Once patients are replete with vitamin D, supplemental vitamin D should be continued and 25(OH)<sub>2</sub>D levels checked yearly [30,148].

## Acid–base and electrolytes

### Acid–base status

Infants and children normally have a relatively larger endogenous hydrogen ion load (2–3 mEq/kg) than do adults (1 mEq/kg); in turn, metabolic acidosis is a common manifestation of CKD in children and an important negative influence on growth through a number of growth factor specific mechanisms, including a reduction in thyroid hormone levels and blunting of the IGF response to GH [168]. Furthermore, studies performed in adults and children have shown that chronic acidosis is associated with increased oxidation of branched-chain amino acids, increased protein degradation [169], and decreased albumin synthesis [170]. Persistent acidosis also has detrimental effects on bone because it alters the normal accretion of hydroxyapatite into bone matrix and causes bone demineralization as bone buffers are increasingly used for neutralizing the excess acid load. Thus it is recommended that the serum bicarbonate level should be maintained at or above 22 mEq/L in children with CKD by supplementing with oral bicarbonate as needed [30].

### Sodium

Sodium requirements in children with CKD are dependent on the underlying kidney disease and the degree of renal insufficiency. Children who have CKD as a result of obstructive uropathy or renal dysplasia are most often polyuric and may experience substantial urinary sodium losses despite advanced degrees of CKD. Sodium depletion adversely affects growth and nitrogen retention [171], and its intake supports the normal expansion of the ECF volume needed for muscle development and mineralization of bone [172]. Fine et al., demonstrated poor weight gain in animals deprived of salt with a resultant decreased extracellular volume, bone mass, and fat mass [173]. Parekh et al., reported the beneficial effect of a dilute, sodium supplemented (2–4 mEq sodium per 100 mL formula), high-volume (180–240/kg per 24 hours, depending on urine output) feeding regimen on the linear growth of 24 young children with severe polyuric CKD. The treated group of patients was able to maintain a nearly normal height SDS despite the presence of significantly impaired kidney function [174]. Therefore infants and children with polyuric salt-wasting forms of CKD who do not have their sodium and water losses corrected

may experience vomiting, constipation, and significant growth retardation associated with chronic intravascular volume depletion and a negative sodium balance [174]. It is important to note that normal serum sodium levels do not rule out sodium depletion and the need for supplementation. Sodium supplementation can be given as chloride or bicarbonate, depending upon the patient's acid–base status.

In contrast, children with CKD resulting from a primary glomerular disease, or those who are oliguric or anuric, typically require a sodium and fluid restriction to minimize fluid gain, edema formation, and hypertension. The prescribed fluid intake is usually a fraction of the calculated maintenance volume adjusted for the degree of oliguria. According to the most recent 2005 Dietary Guidelines, the sodium intake for children older than 2 years should be restricted to <1500 mg (65 mmol) [175], which corresponds to sodium intake of 1–2 mmol/kg per day for those younger than 2 years. These patients should be advised to avoid processed foods and snacks from fast-food restaurants as a substantial amount of sodium can come from salt added during food processing. In support of the recognized association between fast foods and salt intake, a cross-sectional study of dietary intake in the CKiD cohort revealed that the dietary sodium intake increased with age and exceeded the recommended maximum intake in all age-groups [97]; the median sodium intake was 83 mg (3.6 mmol)/kg per day [176]. Fast foods were the largest single source of sodium, contributing 9.4% of the total intake [176]. When stratified by age-group, cheese (10%) was the top contributor to sodium intake in children aged 2–5 years, while fast foods were the main source of sodium for children aged 6–13 (8.8%) and 14–18 (10.2%) years [176].

Infants receiving PD are particularly predisposed to substantial sodium losses, even when anuric. High ultrafiltration requirements per kilogram of body weight result in the removal of significant amounts of sodium chloride. These losses are not adequately replaced through the low sodium content of breast milk (160 mg/L or 7 mmol/L) or standard commercial infant formulas (160–185 mg/L or 7–8 mmol/L) [177]. Therefore infants on PD are at risk of developing hyponatremia that can result in cerebral edema and blindness and must be maintained in neutral sodium balance. Sodium supplementation should be individualized based on clinical symptoms, including hypotension, hyponatremia, and/or abnormal serum chloride levels.

### Potassium

Potassium homeostasis in children with CKD is usually unaffected until the GFR falls to <10% of normal. However, children with renal dysplasia, postobstructive

kidney damage, severe reflux nephropathy, and renal insufficiency secondary to interstitial nephritis often demonstrate renal tubular resistance to aldosterone and may manifest hyperkalemia, even when their GFR is relatively well preserved. The hyperkalemia experienced by these children is exacerbated by volume contraction (and can be particularly common in salt losers) and the majority of the patients respond to salt and water repletion. In patients who are persistently hyperkalemic, dietary potassium intake should be limited. As potassium content is infrequently listed on food labels and cannot be tasted, a list of foods rich in potassium such as chocolates, French fries, potato chips, bananas, green leafy vegetables, dried fruits, and orange juice should be provided to patients and their families. Altering the methods of food preparation, such as soaking vegetables before cooking, helps decrease potassium content. Moderate-to-severe hyperkalemia may require treatment with a potassium binder such as sodium polystyrene sulfonate (SPS) (Kayexalate), patiomer (Veltassa), or sodium zirconium cyclosilicate (Lokelma). In contrast to SPS that exchanges sodium for potassium ions, and can also bind calcium and potentially result in hypocalcemia, patiomer exchanges calcium for potassium ions thus avoiding the provision of a sodium load and the possible inadvertent development of hypocalcemia. At present, patiomer has only been approved for usage in adults and pediatric trials are ongoing.

In the case of infants and young children being fed milk formula, the potassium content of the formula can be reduced by pretreating it with a potassium binder, SPS, or patiomer [178]. It is important to note that pretreatment of milk formula with SPS can reduce the calcium concentration by 8%–29%, and increase the sodium concentration by 86%–300% [179, personal communication VC]. On the other hand, pretreatment with patiomer has no impact on sodium concentration,

while it increases calcium concentration by 19%–43% [personal communication VC]. Alternatively, special milk formulas such as Renastart (VitaFlo USA) or Renalcal (Nestle Health Sciences) that are low in potassium and can be used to minimize the exposure to dietary potassium (Table 34.10) [180].

In children undergoing HD, dietary potassium intake should be distributed throughout the day, as high serum concentrations of potassium can develop when a large quantity of potassium is ingested at one time, regardless of the total daily dietary content. On the other hand, some patients receiving PD may become hypokalemic due to potassium losses in the dialysate and will require potassium supplementation, as hypokalemia has been associated with an increased risk for the development of peritonitis. Finally, if constipated, the patient should be treated aggressively as significant quantities of potassium are eliminated through the gastrointestinal route in patients with CKD.

### Vitamins and micronutrients

Vitamins and minerals are essential for normal growth and development and either a deficiency or an excess can prove harmful. Unfortunately, the vitamin and mineral needs of pediatric patients with CKD are not clearly defined (other than for Vitamin D), and the limited data that are available are derived from patients undergoing maintenance dialysis. Children with CKD are prone to develop vitamin deficiencies because of anorexia and dietary restrictions, while they are also at risk to develop toxic levels of vitamins when the renal clearance is significantly impaired.

All of the water-soluble vitamins except pyridoxine are eliminated by the kidneys and their clearance in patients with CKD is not known. However, most

TABLE 34.10 Milk and selected commercial formula nutrient content per 100 kcal.

Milk/formula	Calories (kcal/oz)	Volume (mL)	Protein (g)	Sodium (mg)	Potassium (mg)	Calcium (mg)	Phosphorus (mg)
Cow's milk	19	159	5.1	79	248	200	148
Human milk	20	150	1.5	25	75	46	20
Similac PM 60/40	20	148	2.2	24	80	56	28
Renastart	30	100	1.6	50	23	22	19
Renalcal	60	50	1.7	3	4	3	5
Nepro	54	56	4.5	59	59	59	40
Suplena	54	56	2.5	44	63	59	40

Conversion mg to mEq: sodium 23 mg = 1 mEq; potassium 39 mg = 1 mEq. Human milk electrolyte composition can vary with maternal diet. Renalcal is a calorically dense, minimized electrolyte formula that should not be used as the only source of complete feeding.

Adapted from Chadha V, Woloshuk RJ, Warady BA. Nutrition in pediatric kidney diseases. In: Mitch WE, Ikizler TA, editors. *Handbook of nutrition and the kidney*. 7th ed. Philadelphia, PA: Wolters Kluwer; 2018. p. 245–8.

water-soluble vitamins are lost during maintenance dialysis and, in turn, are routinely supplemented by special vitamin formulations that do not contain vitamin A and D, such as Nephronex (L Lorens Pharmaceuticals), Nephro-Vite (Allergan Inc.), and Diallyvite (Hillestad Pharmaceuticals Inc.). Studies conducted in the adult dialysis population have provided evidence of low blood concentrations of water-soluble vitamins and minerals because of inadequate intake, increased losses, and increased needs [181,182]. Deficiency of vitamin B<sub>6</sub> can result from poor dietary intake as well as impaired formation and/or increased clearance of pyridoxal phosphate in the dialysis fluid [183]. Vitamin B<sub>12</sub> and folic acid, both of which are important for effective erythropoiesis, differ in their peritoneal clearance; while there can be significant losses of folic acid, only small quantities of vitamin B<sub>12</sub> are lost by this route [184]. Accordingly, supplementation with 0.8- to 1.0-mg folic acid is routinely recommended, while the necessity of vitamin B<sub>12</sub> supplementation remains unsettled. A higher dose of folic acid (2.5 mg/d) has been suggested for children with CKD and on dialysis, as supplemental folic acid has been shown to decrease the elevated homocysteine levels that is commonly seen in patients with renal failure and that is a potential risk factor for cardiovascular morbidity and mortality [185,186]. In contrast, serum thiamine and riboflavin levels have been reported to be normal in PD patients, with or without supplementation, in association with negligible losses during dialysis [187].

Supplementation with vitamin C is occasionally recommended because of the significant quantity that can be lost during PD [188]. It is important to recognize, however, that while adequate levels of vitamin C are necessary for the formation of collagen, an excessive intake of vitamin C in the dialysis population may result in elevated oxalate levels as an end product of vitamin C metabolism and lead to the development of significant vascular complications [189]. Accordingly, vitamin C intake should not exceed 100 mg/d. Vitamin K deficiency is likely in patients who receive frequent antibiotics and has been reported in a small number of adults [190]. Vitamin A levels are usually elevated in patients undergoing PD despite the lack of vitamin A in the vitamin supplement formulation. The elevated levels are a result of the loss of the kidneys normal ability to excrete vitamin A metabolites [191]. Since elevated levels of vitamin A can be associated with the development of hypercalcemia and complications related to a high calcium–phosphorus product, it is critically important to avoid the use of vitamin supplements that include vitamin A.

In children older than 6 years of age undergoing PD, vitamin supplementation has been associated with

normal or greater than normal serum levels of the water-soluble vitamins [188]. However, no published studies have assessed the blood vitamin levels of children undergoing maintenance dialysis in the absence of the use of a vitamin supplement. As most infant milk formulas, including Similac PM 60/40 are fortified with both water- and fat-soluble vitamins, most infants with CKD/ESKD receive the DRI/RDA for all vitamins (including vitamin A) by dietary intake alone. Warady et al. [192] reported on the vitamin status of a group of seven infants undergoing PD; their main nutrient intake was infant milk formula (Similac PM 60/40) and they received a water-soluble vitamin supplement (Iberet; Abbott Laboratories, Abbott Park, IL). The combined dietary and supplement intake exceeded the RDA for the water-soluble vitamins in all but one patient who received only 79% of the RDA for vitamin B<sub>6</sub> because of inadequate formula intake. In all cases, the patient's serum concentrations of the water-soluble vitamins were comparable to or greater than the values reported in normal infants. In addition, the serum vitamin A levels were significantly greater than normal values, despite the lack of supplemental vitamin A.

Aluminum, copper, chromium, lead, strontium, tin, and silicon levels have all been noted to be elevated in patients with CKD, reflecting the fact that their clearance is dependent on an adequate GFR [193,194]. Other trace elements have not been well studied in children; however, zinc levels have been shown to be low in malnourished children and should be monitored and supplemented as necessary [193].

Based on the limited data referred to earlier, the current KDOQI Pediatric Nutrition Guidelines [30] recommend the intake of at least 100% of the DRI for thiamin (B<sub>1</sub>), riboflavin (B<sub>2</sub>), niacin (B<sub>3</sub>), pantothenic acid (B<sub>5</sub>), pyridoxine (B<sub>6</sub>), biotin (B<sub>8</sub>), cobalamin (B<sub>12</sub>), ascorbic acid (C), retinol (A),  $\alpha$ -tocopherol (E), vitamin K, folic acid, copper, and zinc for children with CKD stages 2–5, and those receiving maintenance dialysis. They suggest supplementation of vitamins and trace elements if dietary intake alone does not meet 100% of the DRI or if clinical evidence of a deficiency, possibly confirmed by low blood levels of the vitamin or trace element, is present [30]. As most infant milk formulas are fortified with both water- and fat-soluble vitamins, the majority of infants with CKD (and not yet on dialysis) receive the DRIs for all vitamins (including vitamin A) by dietary intake alone and do not require vitamin supplementation.

## Carnitine

Carnitine is essential for normal mitochondrial function, fatty acid and energy metabolism, and cell

membrane stability [195]. While essential for life, carnitine is a nonessential compound because it can be endogenously synthesized from lysine and methionine in liver, kidney, and brain [196]. However, most of the body's carnitine (approximately 75%) is derived from dietary intake, primarily from the consumption of meat. Carnitine is essentially found in two forms in the body, as free carnitine and as acylcarnitines (compounds in which carnitine is bound, by acyl-binding, to fatty acids of varying size) [197]. Normally, free and acylcarnitines are excreted in the urine in constant proportions so that the serum acyl/free carnitine ratio stays constant. A cross-sectional study in adults showed that the serum total (sum of free carnitine and acylcarnitines), free and acylcarnitine concentrations in the CKD patients were each not different from the values in healthy individuals [198]. In contrast, in patients receiving HD, the serum-free carnitine concentration was significantly lower and the serum acylcarnitine concentration was significantly greater as compared to healthy subjects; as a result the ratio of acylcarnitine to free carnitine, an index of abnormal carnitine metabolism, is dramatically increased in patients receiving HD [198]. Serum acylcarnitines increase in CKD and HD patients primarily because of impaired renal excretion. Serum-free carnitine, on the other hand, is not reduced in CKD but decreases in patients who receive HD because of increased removal during dialysis [198]. While not extensively studied in patients receiving PD, carnitine deficiency seems to be almost as common in these patients as in patients receiving HD. In a study of 34 PD patients matched (age, sex, and dialysis duration) with 34 HD patients, the prevalence of carnitine deficiency was 8.8% in the PD group and 17.7% in the HD group. There was no difference in the distribution of serum total, free, and acylcarnitine concentrations between the two groups [199]. In another study, 20 children ages 2–18 years receiving PD were found to have low plasma free and elevated acylcarnitine at baseline when compared to a healthy matched control group. After a 30-day period of oral carnitine supplementation (50 mg/kg per day), there was a significant increase in plasma levels of both free and acylcarnitine; however, no change was seen in the acylcarnitine to free carnitine ratio [200].

Carnitine deficiency can result in the development of anemia, cardiomyopathy, and muscle weakness [201]. However, most, but not all, of the few pediatric studies that have been conducted on the subject of carnitine deficiency in dialysis patients have provided evidence for an increase in the plasma carnitine level after carnitine supplementation with no associated change in any symptoms [202]. As such, there currently is insufficient evidence to support the routine use of carnitine in either the pediatric CKD or dialysis

patient populations. However, a trial of supplemental carnitine may be indicated when all other causes for the symptoms in question have been excluded, carnitine deficiency has been confirmed, and the patient has been unresponsive to standard therapies [203]. Carnitine deficiency is determined by measurements of plasma free and total carnitine with an acyl:free carnitine ratio greater than 0.4 [i.e., (total – free carnitine) ÷ free carnitine] or a total serum carnitine value less than 40  $\mu\text{mol/L}$  [201].

## Nutrition management

A registered dietitian with experience in pediatric kidney diseases should play the central role in the dietary management of children with CKD/ESKD. In addition to possessing knowledge related to nutritional requirements, this person should also be skilled in the evaluation of physical growth, developmental assessment, and the educational and social needs of this special population. The dietitian must be able to establish a positive rapport with both the child and the primary caretakers to enhance compliance with the recommended nutritional regimen. The focus of the dietitian's treatment plan is determined by the patient's age. In the case of infants, the parents or primary caretaker who is responsible for feeding the child has the greatest interaction with the dietitian; in contrast, adolescents must receive the majority of information directly, as they often eat independently. For children between these two extremes, both the parents and the child are typically involved in different aspects of the dietary management. It is noteworthy that the two most vulnerable groups of patients in terms of the risk for malnutrition are infants and adolescents. While infants are at special risk because of the frequent occurrence of anorexia and emesis, many adolescents have poor eating habits, as mentioned previously.

An individualized nutrition plan taking into account a variety of factors should be developed for each patient by the dietitian in consultation with the physician, patient (when appropriate), and family, with clearly defined short- and long-term objectives. As cultural food preferences play an important role in the family's ability to adhere to dietary changes, dietary instructions should be tailored to help families modify, but not eliminate cultural food preferences. Background information on cultural diets and translated versions of renal diets and food lists are available for reference [204]. The plan should be modified as necessary according to changes in the child's nutritional status, kidney function, dialytic therapy, medication regimen, and psychosocial situation with particular attention paid to any concerns for food insecurity.

Dietary restrictions should be limited as much as possible with a goal of enhancing nutrient intake. Restrictions of nutrients should ideally be imposed only when there is a clear indication, rather than an anticipated need. It is also important to find substitutes for restricted foods so as to maintain an adequate caloric intake. A simple explanation of the role of the nutrient in the body, the rationale for the diet modification, and the desired outcomes to be achieved (e.g., normalization of biochemical parameter, specific amount of weight gain) is helpful in obtaining cooperation of the patient and caretakers, thereby increasing the likelihood of success. Adopting and maintaining changes in eating habits is also easier for a child if family members make similar changes, or at least avoid eating restricted foods in the child's presence. In addition, caregivers outside of the immediate family (e.g., grandparents, school staff, babysitters) should be aware of the diet restrictions and be asked to provide consistency of care in helping the child follow his/her diet. While the ideal goal is full compliance with the prescribed regimen, it is not always a realistic expectation and "partial compliance" is often acceptable. Being very rigid with the dietary prescription adds to parental stress and increases the risk for behavioral eating problems in the young child such as food refusal, gagging, and vomiting.

### Oral supplementation

Infants with CKD requiring fluid restriction or those who have a poor oral intake may require a greater caloric density of their milk formula than the standard 20 kcal/oz. The increase in caloric density should not be achieved by concentrating the milk formula, as this approach will also increase the protein and mineral content. The provision of extra calories can be achieved by adding carbohydrate and/or fat modules to the formula. Glucose polymers such as Polycose (Abbott Nutrition) or SolCarb (Medica Nutrition) have a low osmolality and are generally the initial supplements added to infant formulas. Additional calories can be added in the form of corn oil. Oils containing medium-chain triglyceride are generally not necessary unless there is coexistent malabsorption. However, usage of corn and other oils as additives is not common as they do not mix well with formula and cause problems with tube feedings. Microlipid (Nestle Nutrition), a 50% fat emulsion from safflower oil with 4.5 kcal/mL, and Duocal (Nutricia North America), a fat and carbohydrate combo modular with 5 kcal/g of powder (59% calories from carbohydrate and 41% from fat), are common commercially available products for energy supplementation. The latter is not

approved for infants younger than 1 year. Older infants may tolerate the addition of corn syrup or sugar, which are readily available and inexpensive. The quantity of both carbohydrate and fat modules can gradually be increased to raise the caloric density to as much as 60 kcal/oz [205]. It is important to wait at least 24 hours following each 2- to 4-kcal/oz incremental increase in concentration to enhance patient tolerance of the formula.

Nutritional therapy, irrespective of the route of administration or the caloric density of the formula, should provide a balance of calories from carbohydrate and unsaturated fats within the physiological ranges recommended as the Acceptable Macronutrient Distribution Ranges (AMDR) of the DRI. Recommended AMDR for children older than 4 years are 45%–65% from carbohydrate, 25%–35% from fat (polyunsaturated/saturated ratio of 1), and 10%–30% from protein; children younger than 3 years need a somewhat greater proportion of fat (30%–40%) in their diets to meet energy needs. An adequate amount of nonprotein calories should be provided for protein-sparing effects. It should, however, be noted that during the advanced stages of uremia, the protein-sparing effect of added fat calories may be inferior to the effect of added concentrated carbohydrate calories [38]. Unfortunately, children beyond infancy characteristically refuse the high-calorie carbohydrate supplements. For them, it is often easier to encourage common foods that have a high caloric content, but a relatively low mineral and protein content. Powdered fruit drinks, frozen fruit-flavored desserts, candy, jelly, honey, and other concentrated sweets can be used for this purpose. However, the altered taste acuity associated with uremia may limit the acceptability of these foods. In addition, one may need to avoid high carbohydrate foods in the presence of hypertriglyceridemia. Under these circumstances, unsaturated fats may be the preferred choice of high-calorie food sources. Children and adolescents should also be encouraged to use margarine on popcorn, bread, vegetables, rice, and noodles for added calories.

A variety of calorie-dense (1.8 kcal/mL) preparations such as Nepro and Suplena (Abbott Nutrition) have been formulated specifically for renal patients and are commercially available. Suplena has a lower protein content than Nepro (30 vs 70 g/L) and is preferable for predialysis patients. These preparations are characterized by a low renal osmolar load and a low vitamin A and D content. Although initially produced for patients older than 10 years, they have been successfully used in children as young as 3 years; however, it is advisable to dilute them to half to two-third strength when used in young children. Hobbs et al. reported the successful use of these adult renal

formulas in seven hyperkalemic infants with improved growth and normalization of the serum potassium level [206].

In contrast to energy intake, the protein requirements of children with CKD are usually met by voluntary, unsupplemented consumption. A recently published CKiD experience revealed that the median DPI of children with CKD exceeded recommended levels in all age-groups, particularly among younger subjects [97]. However, if on occasion the protein intake is insufficient due to concomitant phosphorus restriction in a patient with severely impaired kidney function, the protein module, Beneprotein (Nestle Nutrition), a whey protein concentrate, can be added to the formula to increase the protein content. As much as 1 g of Beneprotein, which is equivalent to 0.86 g protein, can be added to each ounce of formula. Semisynthetic diets supplemented with either amino or keto forms of essential amino acid have also been tried to ensure an adequate protein intake. However, the lack of sufficient data in children precludes making any firm recommendation regarding their possible clinical application.

### Enteral nutritional support

Aggressive enteral feeding should be considered if the nutritional intake by the oral route is suboptimal despite all attempts at oral supplementation. The use of enteral support has resulted in maintenance or improvement of SD scores for weight and/or height in infants and young children with moderate-to-severe CKD and those undergoing maintenance dialysis [4,12,19,101,207,208]. In fact, several investigators, including Kari et al. [96], have advocated early enteral feeding at the first sign of growth failure during infancy.

Nasogastric (NG) tubes, [207,208], gastrostomy catheters [209], gastrostomy buttons [210,211], and gastrojejunostomy tubes [212] have all been used to provide supplemental enteral feeding to children with kidney disease with encouraging results. The feeding can be given as an intermittent bolus, or more commonly by continuous infusion during the night. Continuous overnight feeds are generally preferred to allow time during the day for regular oral intake. Historically, the NG tube was used most frequently in infants and young children, as it is easily inserted and is generally well tolerated [208]. Ellis et al. reported the usage of an NG tube by 78% and 68% of children who initiated dialysis at <3 months and 3–20 months of age, respectively [213]. However, this route of therapy is often complicated by recurrent emesis and the need for frequent tube replacement, in addition to the risk of pulmonary aspiration, nasoseptal erosion, and psychological distress of the caretaker because of

the cosmetic appearance. Persistent emesis can be addressed by slowing the rate of formula delivery and by the addition of antiemetic agents such as metoclopramide or domperidone. Additionally, whey predominant formulas can be used as they have been shown to stimulate gastric emptying [214,215].

The gastrostomy tube or button has more recently been used as the enteral route of choice by many clinicians and has the cosmetic advantage of being hidden beneath clothing. Once placed, it can be used within several days. Many, but not all, clinicians recommend that the patient should be investigated for gastroesophageal reflux prior to undertaking gastrostomy placement so that a Nissen fundoplication can be carried out at the same sitting, if required. The reported complications of gastrostomy tubes/buttons include exit-site infection, leakage, obstruction, gastrocutaneous fistula, and peritonitis in patients receiving PD [216,217]. Peritonitis is potentially the most serious complication and is a likely factor inhibiting the more widespread adoption of gastrostomy as opposed to NG feeding in the PD population [218]. In the SCOPE (Standardizing Care to Improve Outcomes in Pediatric ESRD) collaborative analysis, patients with a gastrostomy had a higher incidence of peritonitis on univariate analysis [219]. Warady et al. reported that 11 (24%) of 45 episodes of fungal peritonitis were associated with the presence of a gastrostomy tube or button, but there was no statistically significant correlation between the presence of a gastrostomy and the development of fungal peritonitis [220]. This finding was recently confirmed by a subsequent SCOPE collaborative report on 41 episodes of fungal peritonitis [221]. To decrease the risk of peritonitis, the gastrostomy should be placed either before or simultaneously during PD catheter placement, accompanied by antibiotic and antifungal prophylaxis [30,222]. In addition, it may be better to avoid combining gastrostomy placement and PD catheter placement in a severely malnourished patient until the nutritional status and general immunity of the patient can be improved by other means, such as NG tube feeds [217].

Rees et al. [101], in a study of the IPPN, demonstrated the effectiveness of NG tube and gastrostomy feeding in improving the nutritional status of young (<2 years) children receiving chronic PD. The authors also observed that the use of gastrostomy in contrast to NG tube was associated with better growth, believed to be due to decreased vomiting seen with gastrostomy feedings. However, a recent IPPN report also revealed marked global variation in feeding strategies and the complex relationship between enteral feeding and growth. According to the report, gastrostomy usage was more common in North America, Western Europe, Korea, and New Zealand and was associated with the

development of obesity [12]. BMI SDS at PD initiation was associated positively with eGFR and gastrostomy feeding prior to PD initiation. Finally and surprisingly, the authors also noted that obese, but not underweight, patients were significantly shorter than patients with a normal nutritional status at the initiation of PD [12]. This finding, and similar observations made previously, confirms that correction of growth failure may not always be achievable by just increasing the caloric intake.

A common and serious complication of using any form of enteral tube feeding is a prolonged and potentially difficult transition from tube to oral feeding [223,224]. Regular nonnutritive sucking and repetitive oral stimulation are recommended for all tube-fed infants. A multidisciplinary feeding team consisting of a dietitian, occupational therapist, and behavioral psychologist can help facilitate the transition from tube to oral feeding.

### Alternative routes of nutritional support

The substitution of amino acids for dextrose in the PD fluid and the provision of parenteral nutrition during HD sessions (intradialytic parenteral nutrition; IDPN) are two additional aggressive approaches to nutritional supplementation that have had limited pediatric application. Intraperitoneal nutrition has been evaluated in only a small number of children receiving PD and for a limited period of time [116,117,225]. The quantity of amino acids absorbed from the dialysate routinely exceeded the protein lost in the dialysate. Very little experience with IDPN has been reported in the pediatric population. A short-term study of 10 chronic HD patients, ages 10–18 years, conducted in the Netherlands documented weight gain in 9 patients with no significant change in the plasma amino acid profile [226]. Similarly, Goldstein et al. demonstrated a reversal of weight loss and initiation of weight gain within 6 weeks of IDPN initiation in 3 malnourished adolescents undergoing HD [227]. Future studies may prove these routes of nutritional supplementation to be valuable adjuncts to the oral and enteral routes of therapy.

Finally, children receiving three times a week HD have to endure dietary restrictions that can be removed with daily intensified HD. Fischbach et al. showed significant catch-up growth (mean growth velocity increased from  $3.8 \pm 1.1$  cm/year at baseline to  $14.3 \pm 3.8$  cm/year during the first year) with intensified hemodiafiltration and continued GH therapy in 15 children with a mean age of 8.25 years [228].

# Metabolic management and nutritional support in acute kidney injury

*Wilfred Druml*

Division of Nephrology, Medical Department III, Medical University of Vienna, Vienna General Hospital,  
Vienna, Austria

## Introduction

Acute kidney injury (AKI) is a clinical syndrome that can evolve from many different etiologies and is associated with a broad spectrum of severe short- and long-term consequences [1]. The pattern of renal dysfunction ranges from simply functional, in many instances volume responsive impairment, to gross tubular injury with a complete shutdown of exocrine renal function with the necessity of extracorporeal organ support [2].

Critical for the understanding of the manifold presentations of AKI is the fact that when the complex functions of the kidney, the main regulatory organ of the body for maintaining fluid compartments and electrolyte-homeostasis (*milieu intérieur*) and its multiple endocrine, metabolic, and immunologic tasks are impaired, practically all physiologic pathways and organ functions in the body are affected. Actually, AKI in its more severe forms presents a “pan-metabolic, pan-endocrine, pan-organ syndrome.”

Consequences of AKI thus not only include direct and immediate effects such as an impairment of fluid, electrolyte, and acid–base homeostasis, but also a broad range of endocrine, metabolic, and immunologic complications [3]. Clinically important is the fact that an impairment of renal function causes an augmentation of inflammation, by which secondary damage to other organs (distant organ injury) is induced that, in a vicious cycle, augments renal injury [4,5]. A patient does not (only) die “in AKI”—as was previously often assumed—but also “from” AKI.

AKI, however, is also associated with severe long-term consequences and can exert a dramatic impact on the future life of the patient who survives an AKI

episode. This includes a reduced life expectancy, an impaired quality of life, an increased risk of developing chronic kidney disease (CKD), cardiovascular disease, hypertension and immunological disorders with an increased risk of developing infections, neoplasia, and end-stage renal failure [1,3].

Because of these often dramatic consequences of loss of renal function, prevention of AKI is of utmost importance, and if renal dysfunction has occurred, to reduce the risk of progression of chronic renal disease and when possible to reverse renal functional loss [6]. Moreover, when AKI has occurred, the untoward consequences must be minimized as far as possible to enable and promote recovery of renal function. Within this context the metabolic management of the patients, in addition to nutritional therapy, includes the management of volume status and electrolyte and acid–base balance.

AKI is defined and classified into three stages of severity according to the criteria proposed by the “Kidney Disease: Improving Global Outcomes” initiative (Table 35.1) [2]. Especially important with respect to the prevention, early diagnosis and therapy is the fact that even small changes in renal function (as reflected by minimal increases in serum creatinine of  $>0.3$  mg/dL) have prognostic relevance for the further course of disease and is designated as a “risk stage,” that is, AKI-1. The more severe stages of renal dysfunction are designated as “injury” (AKI-2) and “failure” (AKI-3). If renal replacement is required, it is classified as AKI-3D (Table 35.1). When the pathophysiologic process is ongoing, the syndrome has recently been termed acute kidney disease [7].

The three stages of AKI profoundly differ not only in the clinical presentation but also in the metabolic environment and nutrient requirements of the patient.

TABLE 35.1 Staging of acute kidney injury by Kidney Disease: Improving Global Outcomes Guidelines.

Stage	Serum creatinine	Urine output
1	1.5–1.9 times baseline OR ≥ 0.3 mg/dL (≥26.5 mmol/L) increase within 48 h	<0.5 mL/kg/h for 6–12 h
2	2.0–2.9 times baseline	<0.5 mL/kg/h for ≥ 12 h
3	3.0 times baseline OR Increase in serum creatinine to ≥ 4.0 mg/dL (≥353.6 mmol/L) OR Initiation of renal replacement therapy OR In patients <18 years, decrease in estimated GFR to <35 mL/min/1.73 m <sup>2</sup>	<0.3 mL/kg/h for ≥ 24 h OR Anuria for ≥ 12 h

GFR, Glomerular filtration rate.

Thus the metabolic management and nutrition support must be adapted to these different stages of AKI. Moreover, because of the broad pattern of etiologies and clinical presentations of AKI patients and the dynamic, often fluctuating course of their diseases, the therapeutic regimens, and especially the metabolic management and nutrition support for these patients, must be individualized for each patient and at each time point during the patient's clinical course.

A further point that should be considered is the fact that the epidemiology and clinical presentation of AKI may fundamentally differ between community acquired conditions (often in the context of preexisting chronic systemic disease), hospital-acquired AKI (mostly more complex causes) and intensive care unit (ICU) acquired AKI with the latter often being caused by severe infections/septicemia and presenting as a part of multiple organ dysfunction syndrome (MODS) [8–10]. Nevertheless, many patients with AKI are not critically ill and are cared for on open wards. These patients need a stage-specific approach to their nutritional management.

As a consequence of this clinical heterogeneity nutritional support of AKI patients is one of the most challenging situations in clinical nutrition. However, although AKI is a commonly occurring disorder, there are very few systematic studies concerning its nutritional management. Thus most recommendations are not based on high-quality randomized controlled trials (RCTs), but must largely rely on expert opinion.

The most recent recommendations from international nutrition societies (ASPEN, ESPEN) on nutrition support in critically ill patients address only single points in nutritional support for patients with AKI [11,12]. Specific guidelines for patients with AKI issued by ASPEN are mostly outdated and are currently undergoing revision,

ESPEN recently has published revised recommendations [13,14].

In this chapter a stage-specific approach to the metabolic management for prevention, therapy, and nutrition support of patients with acute renal dysfunction is summarized and a more holistic metabolic approach beyond classical nutritional interventions is proposed.

### Metabolic management in the prevention of AKI and the therapy of AKI/risk stage AKI-1

In consideration of the severe short- and long-term consequences of AKI, the major impact of AKI on morbidity and mortality, the possibility of continuing risk of renal injury, and the potential for permanent loss of renal function, the restoration of renal function is of major clinical importance [6]. To restore renal function, it is important to note that many metabolic and nutritional interventions may have a previously mostly unrecognized role.

There is no effective pharmacologic therapy for AKI [6]. Therefore the general management of the patient and the optimization of hemodynamics, the volume state, respiratory function, the metabolic balance, including electrolyte-homeostasis and acid–base equilibrium and the avoidance of nephrotoxic medicines, are the most important means to preserve microcirculation and to preserve or restore kidney function [2] (Table 35.2).

### Preconditioning

Preconditioning encompasses strategies, which applied before an injurious event (such as elective surgery and contrast media application) enhance the organ tolerance to subsequent insults. Most extensively

**TABLE 35.2** Metabolic management in the prevention of acute kidney injury (AKI) and therapy of AKI-1 (risk stage).

- Preconditioning (?)
- Volume therapy
  - Infusion solutions: chloride reduced, no artificial colloids
  - Avoidance of hypovolemia and hypervolemia
- Prevention/correction of electrolyte imbalances
  - Potassium, phosphate, magnesium
- Prevention/correction of deficiency states
  - Thiamine, vitamins B6 and C, folate?
- Prevention/correction of metabolic acidosis?
- Prevention/correction of hyperglycemia
- Early start of (whenever possible) oral or enteral nutrition
- Avoidance of hypercaloric nutrition in the early phases
- Higher protein-/amino acid intake in the early phases?

investigated was remote ischemic preconditioning in the prevention of AKI. Results from RCTs and subsequent metaanalyses unfortunately were quite conflicting [15].

A further type of preconditioning is dietary restriction (DR), which extends life span and increases resistance to multiple forms of stress. Animal experiments have shown that with even brief periods of DR both calorie and protein restriction (PR) can prevent renal injury [16,17]. In a first RCT, patients scheduled for heart surgery were either subjected to caloric restriction (60% of calculated requirements) or received an ad libitum control diet for 7 days before surgery [18]. the primary endpoint, the rise in serum creatinine within 24 hours was negative; however, the further rise within 48 hours was lower ( $P < .03$ ). There were no other differences in clinical relevant endpoints between the two groups. Unfortunately, the absolute difference in caloric intake was not assessed.

Whether a potential protective effect of DR for preserving renal function is related to caloric restriction or rather to PR remains to be shown. In any instance, DR is more of theoretical interest, rather of limited clinical relevance, which could potentially at best be an intervention for a rather small group of well nourished patients before hospital admission for elective surgery and not for patients at risk for AKI within the hospital (see next).

## Volume management

Obviously, volume management plays a central role in the prevention of AKI. However, not only hypovolemia but also hypervolemia is of importance in deterioration of renal function [19].

*Infusion solutions for prevention of AKI:* The type of infusion solutions has gained much interest in recent years. It has become clear that artificial colloids used for volume resuscitation can exert a nephrotoxic effect by inducing nephrosis-like lesions in the kidney,

including tubular swelling and necrosis, by intracellular and intratubular accumulation of colloids. Several countries as well as the European Union have released warnings and restrictions for the use of artificial colloids in ICU patients. Whether the physiological and natural colloid human albumin exerts advantages in this regard is the subject of much debate and remains unsettled [20].

Thus in prevention and management of early stages of AKI, crystalloid infusion solutions are preferable. However, from a metabolic point of view, the type of crystalloid is relevant in respect to prevention of AKI. Chloride was shown to be a selective vasoconstrictor of renal vessels [21,22]. Normal saline, as compared to a chloride-reduced “balanced” infusion solution, reduced renal cortical perfusion in healthy adults [23]. Normal saline as the main infusion solution may increase renal injury both in noncritically ill and critically ill patients [24,25]. Thus a lower chloride infusion regime by using balanced electrolyte solutions, such as lactated Ringer’s, is preferable for patients at risk of AKI [6].

## Electrolyte-homeostasis and acid–base balance

Until recently, little attention has been given to the importance of maintaining electrolyte balance in the prevention of AKI. In experimental studies, deficiency states of magnesium, potassium, and phosphate each can augment renal injury [26]. Avoidance of magnesium deficiency may prevent the development of AKI [27]. Thus deficiencies of these electrolytes should be prevented and/or corrected.

*Acidosis:* There is a decade-old discussion on the potential of intravenous bicarbonate to prevent AKI. This type of intervention should be distinguished from alkalization therapy for metabolic acidosis. In animal experiments, acidosis aggravates renal injury after ischemia–reperfusion injury [28].

Interest in this matter was stimulated by a large RCT, where the correction of severe metabolic acidosis ( $\text{pH} < 7.2$ ) in critically ill patients using bicarbonate infusions reduced the risk of renal replacement therapy (RRT)-dependent AKI-3D and improved prognosis in patients with AKI-2–3 [29]. Whether this protective effect is mediated by the lower frequency of hyperkalemia as an indication for RRT or whether alkalization per se may exert a direct nephroprotective potential remains to be shown. Given the fact that even mild acidosis in humans is associated with such adverse events as negative protein balance, it could be argued that even mild acidemia probably should be avoided in patients with or at increased risk for kidney injury [30].

## Hyperglycemia

Hyperglycemia interferes with endothelial structure and functions, compromises renal autoregulation, promotes oxidative stress and inflammation, and can aggravate renal injury. These detrimental effects of hyperglycemia on the kidney have been delineated in many animal experiments [31]. Clinical studies in various groups of acutely ill patients indicate that stress-induced hyperglycemia is associated with an increased risk of kidney damage and the development of AKI [32]. Hyperglycemia certainly is a cofactor that increases the susceptibility to renal injury.

In a secondary analysis of two larger RCTs on glucose management in critically ill patients, tight glucose control was associated with a 40% lowered incidence of AKI and a reduced need for RRT [33]. Although a nephroprotective effect of lowering blood glucose concentrations has not been uniformly confirmed in all studies, there is agreement that glucose concentrations should be kept below 180 mg/dL in any acutely ill patient [11,12]. Accordingly, correction of hyperglycemia is included in all recommendations for prevention and conservative therapy of AKI and constitutes a component of all treatment guidelines for the prevention of AKI [2,34]. Since blood glucose concentrations fluctuate in hospitalized patients, some institutions aim for a blood glucose target of 150 mg/dL to reliably maintain the glucose level below 180 mg/dL.

## Endocrine/metabolic interventions

Various endocrine interventions to prevent the development of AKI and/or hasten renal regeneration have been evaluated. In experimental models of AKI, interventions such as thyroxine, recombinant human growth hormone (rHGH), epidermal growth factor (EGF), insulin-like growth factor (IGF)-1, hepatocyte

growth factor, or erythropoietin (EPO) have been shown to prevent renal injury or to accelerate tubular regeneration.

In none of the (mostly older) clinical studies have these beneficial effects been confirmed. In a small pilot study, infusion of rHGH reduced protein catabolism and improved nitrogen balance [35]. However, administration of rHGH was associated with increased mortality of critically ill patients, many of whom had AKI [36]. A multicenter study of administering IGF-1 to AKI patients was terminated early because of the lack of benefit [37]. Administration of triiodothyronine that could potentially upregulate the EGF receptor expression was not only ineffective in patients with AKI but actually increased mortality [38]. Finally, in a large multicenter RCT in AKI patients, EPO failed to exert any clinical benefit [39].

In animal experiments and in some clinical investigations (contrast media exposure, perioperative patients), several nutritional molecules, mainly antioxidants, such as vitamin C, vitamin E, selenium, zinc or resveratrol, have been shown to protect against renal injury [40,41]. However, these beneficial effects have not been confirmed in patients in large RCTs, and none of these interventions has become standard clinical care.

## Nutrition in the prevention of AKI and therapy of AKI-1

Nutrition therapy (oral/enteral/parenteral) in prevention and in the early stage of AKI-1 is not fundamentally different from that in other patient groups [11,12]. Nevertheless, in respect to preservation of renal function, some points should be considered.

### Initiation and route of nutrition support

Whenever possible, oral or enteral nutrition should be used. In experiments in animals, enteral nutrition increased renal perfusion and improved renal function [42]. As in other acutely ill patients, nutrition support should be started early, but at a low rate and the nutritional intake should be increased slowly according to the individual tolerance of the patient [43].

In a large RCT comparing permissive underfeeding (but a comparable protein intake) with full caloric nutrition in critically ill patients, subjects receiving full nutrition from the beginning of their nutritional support had a higher rate of AKI requiring RRT [44]. This was confirmed in subsequent studies. Hence, it is important to note that an early high energy intake may increase the risk of developing AKI [45].

A current controversy relates to the question of the optimal protein/amino acid intake in these patient groups and whether a high intake may be protective by activating renal reserve capacity (i.e., the percentage increase in renal function in a postabsorptive patient after taking a defined protein load) [46].

In patients with cirrhosis of the liver, an amino acid infusion increased renal plasma flow by 32% and glomerular filtration rate (GFR) by 22% [47]. A small pilot study in critically ill patients had suggested that a higher amino acid intake (about 2 g/kg/d) lowers serum creatinine, increased diuresis and lowers the need for diuretics [48]. A large randomized controlled study using an intravenous amino acid infusion of 1 g/kg/d in addition to the protein intake associated with nutrition support (about 1 g/kg/d) improved renal function during the first 4 days but had no effects on “hard” endpoints, such as implementation of RRT, length of hospital stay or survival [49].

In a post hoc analysis of this study the increased amino acid intake protected against the development of AKI and improved outcome in those patients who did not show renal injury at the start of therapy [50]. In a recent study, cardiac surgery patients received an amino acid infusion immediately after induction of anesthesia [51]. Duration of AKI was shortened, estimated GFR and urine output were significantly improved after surgery, but again, the more relevant clinical endpoints were not affected. Certainly, more evidence is needed from RCTs, and for the time being no definite recommendations can be given concerning administration of larger amounts of protein or amino acids in these patient groups for the prevention of AKI.

In various older experiments in animals, it was suggested that some amino acids, such as arginine, glutamine, or taurine, may exert specific nephroprotective properties beyond just providing substrates for protein or peptide synthesis, nitrogen and carbon for urea synthesis, and stimulation of renal reserve capacity. Arginine (and also glutamine by improving renal arginine metabolism) has been of particular interest. Arginine, by producing nitric oxide, might potentially preserve renal perfusion and tubular function during either nephrotoxic or ischemic injury, whereas inhibitors of nitric oxide synthase might exert an opposite effect [52]. However, evidence from clinical investigations is scarce and controversial, and none of these approaches is currently used clinically [53].

Fish oil-containing lipid emulsion may reduce the risk of renal injury in animal models of AKI [54]. However, convincing clinical evidence concerning nephroprotective effects of fish oil in AKI is lacking.

Preexisting deficiency states (electrolytes, micronutrients, such as thiamine) should be corrected to avoid

untoward side effects of malnutrition and the development of a refeeding syndrome [55]. In a secondary analysis of an RCT, thiamine supplementation in critically ill patients reduced the incidence of AKI [56].

Maintaining metabolic balance is also important in noncritically ill patients, and standard oral nutritional supplements (ONS) can be used if required.

## Nutrition solutions

In these patient groups with this low stage of AKI, no specific nutritional preparations should be used for enteral or parenteral nutrition (PN).

### Metabolic support in AKI stages 2 and 3 without the need for renal replacement therapy

The more severe stages of a renal injury AKI-2–3 in patients who do not need RRT are extremely frequent. By definition, patients with these AKI stages are clinically unstable, and careful management is crucial. There are almost no systematic studies concerning the metabolic management and nutritional support in these stages of AKI. The general management of these patients with AKI is as delineated previously and must be a leading goal of therapy (Table 35.1). Even in these stages of AKI, a primary goal must be the stabilization or improvement of renal function; the measures to attain this aim are not fundamentally different from those used in the management of other clinically unstable acutely ill patients.

In these stages of AKI, maintaining a balanced metabolic environment (with regard to electrolytes, glucose, triglycerides, acid–base balance) also must be a primary goal of therapy. Hyperglycemia again is a risk factor for AKI. Periprocedural hyperglycemia increases the risk of developing AKI or of intensifying the severity of AKI during surgery, ischemia, or exposure to nephrotoxins [57,58]. With regard to acid–base balance, in a large cohort analysis, alkalization therapy in patients with sepsis and severe metabolic acidosis (pH < 7.2) was associated with improved survival in patients with AKI-2–3 [59].

## Nutrition support

Patients with AKI-2–3 commonly are unstable and have high variability in their clinical course; their renal injury may be stabilized, improve or progress to AKI requiring RRT. In these stages, it is of utmost importance to adapt the metabolic management and nutritional support to the individual condition of each

patient; the modern postulate of “personalized care” is especially relevant for these phases of AKI.

It has been a widely held opinion that at the risk of sacrificing renal function in these stages of AKI, RRT should be started early to enable adequate nutritional support. In general, such a view can no longer be maintained. Each type of RRT is associated with a specific pattern of complications that are often serious; patients on RRT have increased mortality. Thus RRT should only be used when it is necessary [60]. Patients who have a chance for stabilization or even improvement of renal function should be identified, and nutritional therapy must be adapted to avoid progression of renal insufficiency or development of uremic symptoms.

### Initiation and route of nutrition support

For more stable patients who are not hypercatabolic patients (AKI-2 and early AKI-3) and who are cared for on an open ward, oral nutrition should be started at a low rate and adapted slowly according to the individual tolerance of the patient. Of special importance, protein intake should be initially low (0.3–0.4 g/kg/d) and increased slowly, if at all, according to SUN (serum urea nitrogen). Some experts recommend using supplements of essential amino acids or keto-acids during this phase of AKI. Again, metabolic balance (electrolytes, acid–base, micronutrients, avoidance of hyperglycemia) must be carefully observed and managed in these patients.

In critically ill, unstable patients, nutritional support should be started early, but at a low rate and, again, should be increased slowly according to the individual tolerance of the patient.

**Energy intake:** In unstable stages of AKI-2–3 patients who do not need RRT, full “normocaloric” nutrition should not be pursued or forced. Rather, in analogy to other critically ill patients, a mild “permissive” hypoalimentation should be aimed at where according to the tolerance of the patient about 50%–70% of calculated or measured energy expenditure should be provided [11]. An exaggerated energy intake can induce a further deterioration of renal function in these AKI stages [45].

**Glucose intake:** As was shown many years ago, glucose infusion during ongoing renal injury can aggravate renal tubular damage [61]. In contrast, a glucose-reduced nutritional regimen may decrease the risk of AKI in critically ill patients [62].

**Protein intake:** Many years ago, animal experiments demonstrated that a high amino acid intake during the injury stage of AKI can aggravate renal damage and uremic toxicity (amino acid paradox) [63]. In

agreement the abovementioned RCT that demonstrated a positive effect of a high amino acid infusion on renal function and prognosis in patients with no or minimal renal injury found negative consequences of a high intake in patients with more advanced renal impairment [50].

A secondary analysis of a large RCT comparing the effect of early versus late PN in intensive care patients revealed that an early high amino acid intake was associated with an increased need for RRT. Most of the additional amino acids provided did not enhance anabolism but increased urea generation [64]. Thus a high protein intake in this phase of AKI may increase renal injury and enhance the need for RRT.

In a large multicenter RCT evaluating the effects of a combination of enteral and parenteral glutamine in critically ill patients, mortality was increased during glutamine supplementation in patients who had kidney injury at their enrollment into the study [65].

The intake of protein/amino acids in AKI patients must be monitored regularly by measuring serum or plasma urea concentrations and be modified accordingly. Usually, the protein intake should not be higher than 0.6–1.0 g/kg/d [14]. Neither intravenous nor enteral glutamine should be provided in patients with AKI-2–3 [11].

**Nutrition solutions:** International societies do not recommend the use of specific “nephro” diets (for details vide infra) but rather standard solutions for both enteral and PN in AKI-2–3 patients.

Amino acid solutions adapted to uremic metabolism and with a high content of anabolic essential and conditionally essential amino acids are available in some countries [66]. Theoretical advantages, such as a normalization of plasma amino acid pattern, a reduction of urea formation, and improved protein synthesis, could not be confirmed in larger studies using relevant clinical endpoints.

For ONS/enteral nutrition, there are specific commercially available diets designed for predialysis CKD patients (CKD-3–5) (see next). These diets are low in electrolytes (sodium, potassium, phosphate), have a low-protein content, and potentially might display some metabolic advantages in more stable AKI-2–3 patients, but systematic studies are not available.

### Metabolic management and nutritional support in patients with AKI-3 (and CKD-5) requiring renal replacement therapy (AKI-3D)

The traditional indication for nutritional support in AKI involves more clinically stable patients with established AKI-3 who require RRT (AKI-3D). A very complex metabolic environment is present in these

patients, and both the impact by AKI per se and of RRT on their metabolism and nutrient balances should be considered when designing a nutritional prescription.

### Metabolic alterations specifically induced by acute renal dysfunction

AKI is a syndrome, a complication that occurs with various etiologies and in heterogeneous clinical situations. Hence, the metabolism of AKI patients is affected not only by renal dysfunction but also by the type and intensity of RRT, the underlying disease process, associated comorbidities, dysfunctions of other organs, and such complications as infections.

There are inherent problems with the mostly older studies on metabolism in AKI. Animal experiments are hardly representative of the more prolonged clinical cases of AKI, particularly in cases treated with RRT. Moreover, unlike with humans with AKI, in animal studies of AKI, often the only clinical disorders in the animals were AKI and the technique used to create AKI.

Nevertheless, renal dysfunction per se is associated with a broad spectrum of specific metabolic alterations starting at a GFR of about 50 mL/min or lower. The main metabolic alterations are summarized in Table 35.3. Basically, AKI is a systemic syndrome in

which more or less all physiologic functions, endocrine and metabolic pathways, and organ functions are affected. Moreover, the various types of RRT exert a pronounced impact on metabolism and nutrient balances (see next) (Table 35.4). Taken together, AKI often presents a proinflammatory, prooxidative, and hypercatabolic state that exerts a fundamental effect on the course of disease and development of complications and is also associated with a specific, “attributable” mortality.

### Energy metabolism in patients with acute kidney injury

In experimental animals, AKI tends to decrease oxygen consumption even when hypothermia and acidosis are corrected (uremic hypometabolism) [67]. Remarkably, in the multiple organ failure syndrome, oxygen consumption is significantly lower in patients with AKI than in those without impairment of renal function [68].

In patients with uncomplicated AKI, however, resting energy expenditure (REE) is within the range of healthy subjects. In patients with sepsis and associated AKI, oxygen consumption is increased by approximately 20%–30% as compared to subjects with uncomplicated AKI [69]. Energy expenditure is remarkably similar in AKI patients without or with RRT [70].

TABLE 35.3 Important metabolic abnormalities induced by acute kidney injury.

- Increase in protein catabolism
- Peripheral glucose intolerance/increased gluconeogenesis
- Inhibition of lipolysis and retarded clearance of plasma fat
- Depletion of the antioxidant system
- Induction of an inflammatory state
- Impaired immunocompetence
- Complex endocrine abnormalities: hyperparathyroidism, insulin resistance, erythropoietin resistance, resistance to growth factors, etc.

TABLE 35.4 Enhanced protein catabolism in acute kidney failure: contributing factors.

- Impairment of metabolic functions by uremic toxins
- Acute-phase reaction—systemic inflammatory response syndrome (activation of cytokine network)
- Augmentation of inflammation by AKI
- Endocrine factors
  - Insulin resistance
  - Increased secretion of catabolic hormones (catecholamines, glucagon, glucocorticoids)
  - Hyperparathyroidism
  - Suppressed release/resistance to growth factors
- Acidemia
- Inadequate supply of nutritional substrates
- Renal replacement therapy
  - Release of proteases
  - Loss of nutritional substrates
  - Inflammatory reaction (blood–membrane interactions)

AKI, Acute kidney injury.

These data indicate that there is little if any change in energy metabolism in patients from the AKI per se, and oxygen consumption is mainly determined by the underlying disease and associated complications [71]. In contrast to several other acute disease processes, there is actually a tendency to decrease than to increase energy expenditure with AKI.

Currently available formulas for estimating energy expenditure are inaccurate in patients with AKI [70]. Measurement of REE by using indirect calorimetry is recommended by several nutrition societies which, however, at the present time, is rarely available in clinical practice [72].

### Energy requirements in patients with acute kidney injury

During nutritional support of acutely ill patients, the intake of energy substrates should never exceed actual energy expenditure. Complications, if any, from slightly underfeeding are less deleterious than from overfeeding [73,74]. Increasing energy intake from 30 to 40 kcal/kg BW/d in patients with AKI increases the rate of metabolic complications, such as hyperglycemia and hypertriglyceridemia, and has no beneficial effects [75].

Patients with AKI should receive 20 to a maximum of 30 kcal/kg BW/d [76]. Even in hypermetabolic conditions such as sepsis or the MODS, energy expenditure rarely is higher than 130% of calculated basic energy expenditure, and thus energy intake should not exceed 30 kcal/kg BW/d.

During continuous RRT (CRRT) the use of citrate anticoagulation can be associated with an additional energy intake from the citrate infusion, which although difficult to quantify is estimated as up to 400 kcal/d (vide infra) [77]. These calories and other nontraditional nutritional sources of energy, such as additional glucose infusions or sedation with propofol, which contains a lipid emulsion, must be considered when calculating the energy intake in nutritional support.

### Protein- and amino acid metabolism in acute kidney injury

A leading feature of the metabolic alterations of AKI is the enhancement of protein catabolism with excessive release of amino acids from skeletal muscle and sustained negative nitrogen balance [78]. Amino acids are redistributed from muscle tissue to the liver where hepatic extraction of amino acids from the circulation, hepatic gluconeogenesis and ureagenesis are increased. Moreover, protein synthesis is impaired in AKI [79].

Amino acid transport into skeletal muscle is reduced in AKI. This abnormality can be linked both to insulin resistance and to a generalized defect in ion transport in uremia [80]. Moreover, there are specific alterations of amino acid metabolism, such as the impairment of conversion of phenylalanine to tyrosine and, because circulating arginine is derived mainly from the kidney, reduced arginine synthesis [81]. The elimination of amino acids from the intravascular space is altered [82]. As expected from the increased hepatic extraction of amino acids, overall amino acid clearance and clearance of most glucogenic amino acids are enhanced, but the plasma clearance of phenylalanine, proline, and valine is decreased in AKI. As a consequence of these metabolic alterations, imbalances in amino acid pools in plasma and in the intracellular compartments occur, and a typical plasma amino acid pattern is observed in AKI [83].

### Mechanisms of protein catabolism in acute kidney injury

The causes of hypercatabolism in AKI are complex and manifold and present a combination of unspecific mechanisms induced by the acute disease processes, the acute-phase reaction, the systemic inflammatory syndrome, acidemia, the underlying illness/associated complications, specific effects induced by the acute loss of renal function, and, finally, by the type and intensity of RRT (Table 35.4).

A dominant mechanism for amino acid hypercatabolism is the stimulation of hepatic gluconeogenesis [78]. In healthy subjects and in patients with advanced CKD, hepatic gluconeogenesis ceases with a sufficient infusion of exogenous glucose. In contrast, in dogs with AKI, hepatic glucose formation is only decreased but not halted by exogenous glucose, and gluconeogenesis from amino acids an associated muscle catabolism persists even during glucose infusion [84]. These findings have important implications for nutritional support in patients with AKI-3 because it is impossible to achieve a positive nitrogen balance during the acute phase of the disease.

Several additional catabolic factors are operative in AKI. The secretion of catabolic hormones (catecholamines, glucagon, glucocorticoids), hyperparathyroidism (which is also frequently present in AKI), suppression and/or decreased sensitivity to growth factors, and the release of proteases from activated leukocytes all can contribute protein breakdown [85]. An important stimulus of muscle protein catabolism is insulin resistance. In an animal model corresponding to clinical AKI-3 muscle, the maximal rate of insulin-stimulated protein synthesis is depressed and protein

degradation is increased [86]. An inefficient intracellular energy metabolism also stimulates protein breakdown and interrupts the normal control of muscle protein turnover.

As in other acute disease processes, inflammatory mediators, such as tumor necrosis factor- $\alpha$  and interleukins, play a central role in protein and amino acid hypercatabolism. However, in comparison to other acute disease states, this inflammatory reaction is augmented in AKI, both because the kidneys play an important role in the catabolism of cytokines and because cytokine release is stimulated during tubular injury [87,88].

Metabolic acidosis is a major cause of muscle protein catabolism in CKD through activation through the glucocorticoid-dependent ubiquitin–proteasome pathway [89,90]. The role of acidosis on metabolism in the context of AKI remains to be defined and the optimal bicarbonate concentration is unknown. In patients on RRT, acid–base balance is usually well controlled and can be adjusted as desired. In addition to its negative effects on protein balance, acidosis may be associated with a broad pattern of untoward side effects, on bone and mineral metabolism, glucose tolerance, lipolysis, and hormone secretion and action.

Finally, the type, frequency, and intensity of RRT can profoundly affect protein metabolism and nutrient balances in patients with AKI. Aggravation of protein catabolism, in part, is mediated by the loss of nutritional substrates during RRT, but, both the activation of protein breakdown and the inhibition of protein synthesis in muscle can be induced by RRT (see next) [91].

### Clinical studies on protein catabolism in acute kidney injury

Several studies have tried to quantify protein catabolism in critically ill patients with AKI to define the optimal intake of amino acids/protein in these patients. In most of these investigations, net protein catabolism (i.e., the difference between protein synthesis and protein degradation) was estimated by calculating urea nitrogen appearance or urea kinetics in patients on intermittent hemodialysis (HD) [92,93].

Net protein catabolism in these investigations was extremely variable and indicated that the main mechanisms of protein breakdown are much more related to the underlying disease process and associated complications and not to AKI per se. Nevertheless, as detailed previously, the presence of AKI modifies or augments the underlying inflammatory state and promotes protein breakdown.

The mean net protein catabolic rate (with abroad range of deviation) was approximately 1.5 g/kg BW/d

in most investigations [94–97] but also was higher, about 2.0 g/kg BW/d in some studies [98]. Taken together, there are wide variations in net protein catabolism between individual AKI patients and also in the same patient during the course of the illness [95].

### Amino acid/protein requirements in patients with acute kidney injury

The most controversial question regarding nutritional support in patients with AKI concerns the optimal intake of amino acids and protein. Only a few studies have attempted to define requirements, and there are no adequately designed and powered RCTs available in this field. A previous dogma, that protein intake should match protein catabolism, has never been confirmed in any acutely ill patient group, including in patients with AKI [99,100].

Guidelines from ASPEN in 2010 state, “intake should be adjusted according to catabolic rate, renal functions, and dialysis losses” [13]. More recent guidelines provide a “standard recommendation for protein (1.2–2.0 g/kg BW/d)” for patients without RRT and “up to a maximum of 2.5 g/kg BW/d” for AKI patients on RRT [12]. In contrast, European guidelines recommend 1.3–1.5 (with a maximum of 1.7) g protein/kg/d, which includes 0.2 g/kg/d to compensate for RRT-associated amino acid losses [14]. The level of evidence for all these recommendations is low.

The current ASPEN recommendation for a high protein intake in patients with AKI is mainly based on a study by Scheinkestel and coworkers [101]. However, this is a small and not adequately randomized trial that evaluated the effect of three levels of protein/amino acid intake (1.5, 2.0, and 2.5 g/kg BW/d) on nitrogen balance and outcome. Most patients were studied sequentially. Nitrogen balance was inversely related to energy expenditure and positively related to protein intake. Not surprisingly, nitrogen balance was positively associated with ICU- and hospital survival (but not in a multivariate analysis), and a causal relationship of the amount of protein/amino acids and clinical outcome cannot be concluded from this investigation.

Again, it must be stressed that hypercatabolism cannot be overcome by simply increasing protein or amino acid intake even in patients with normal kidney function. There are no proven benefits of excessive intakes in AKI patients, which increase the accumulation of waste products with the potential of aggravating uremic complications, inducing a hyperammonemic state, and increasing the need for dialysis that, in turn, increases nutrient losses and stimulates muscle protein degradation. Today, for

nutritional research, nitrogen balance is rather a surrogate parameter than a primary endpoint.

### **Carbohydrate metabolism**

Glucose metabolism in AKI is also affected both by nonspecific mechanisms mediated by the acute disease state and by the specific effects of acute uremia. A major abnormality is insulin resistance; plasma insulin concentrations are elevated, the maximal insulin-stimulated glucose uptake by skeletal muscle is decreased and muscular glycogen synthesis is impaired [102]. The severity of insulin resistance in patients with AKI is correlated with the mortality rate [103].

A second feature of altered glucose metabolism in AKI is accelerated hepatic gluconeogenesis mainly from conversion of amino acids released during protein hypercatabolism. Hepatic extraction of amino acids and their conversion to glucose and urea are all increased in AKI. As discussed earlier, in contrast to the nonuremic state and CKD, hepatic gluconeogenesis in AKI cannot be suppressed completely by exogenous glucose infusions [84]. Metabolic acidosis also affects glucose metabolism in AKI by further decreasing glucose tolerance.

Alterations in glucose and protein metabolism in AKI are interrelated. Several factors activating protein catabolism contribute to impairment of glucose metabolism. As a consequence of these metabolic alterations, hyperglycemia is often present in AKI, and insulin infusions for glucose management may become necessary in many patients.

Finally, the metabolism of insulin is abnormal in AKI; endogenous insulin secretion is reduced in the basal state and during glucose infusion [104]. Because the kidney is a main organ of insulin disposal, insulin degradation is decreased; but surprisingly, insulin catabolism by the liver is also consistently reduced in AKI. The resulting elevations in plasma insulin concentration may explain the normal blood glucose levels in many patients with AKI.

### **Lipid metabolism**

AKI is associated also with specific alterations in lipid metabolism. Total plasma triglyceride concentrations and triglyceride content of plasma lipoproteins, especially VLDL, are increased, while total cholesterol and in particular HDL cholesterol are decreased [105].

The major cause of lipid abnormalities in AKI is an impairment of lipolysis. The activities of both lipolytic systems, peripheral lipoprotein lipase and hepatic triglyceride lipase, are decreased to less than 50% of

normal [106]. This impairment of lipolysis in AKI is in contrast to most other acute disease states in which lipolysis usually is augmented. Nevertheless, fatty acid oxidation is not impaired in AKI [70]. Metabolic acidosis may contribute to the impairment of lipolysis in AKI by further inhibiting lipoprotein lipase.

Particles of artificial fat emulsions used in PN are degraded similarly to endogenous VLDL. Thus the nutritional consequence of the impaired lipolysis is a delayed elimination of intravenously infused lipid emulsions [107]. The clearance of fat emulsions is reduced by more than 50% in patients with AKI. Moreover, relevant for enteral nutrition is that intestinal fat absorption is retarded, at least in experimental uremia [108].

Abnormal carnitine levels or metabolism does not contribute to the development of lipid abnormalities in AKI [109]. In contrast to CKD, plasma carnitine levels often are increased in AKI. This might be mediated not only by an increased release from muscle tissues during catabolism but also by an activated hepatic carnitine synthesis. There is a substantial loss of carnitine during various RRT modalities and a deficiency both of total and free carnitine may develop during prolonged CRRT [110].

### **Micronutrients and the antioxidant system in acute kidney injury**

Only observational studies of plasma micronutrient concentrations in various heterogeneous groups of patients with AKI are available [98,111,112]. Most of these studies were conducted in patients receiving RRT. Some studies measured micronutrient losses during RRT but in poorly defined clinical situations (vide infra) [113–115]. The results of these studies are extremely variable and in part even contradictory. In fact, little is known about the effect of AKI per se on micronutrient metabolism. Micronutrient requirements in patients with AKI are not defined, and evidence-based recommendations cannot be given.

By definition, micronutrients (water- and lipid-soluble vitamins, trace elements) are essential components of nutrition, and any nutritional regimen for patients with AKI must be complete and contain these substances. Low plasma levels do not necessarily reflect a deficiency state, because micronutrients, such as selenium or vitamin C, may be redistributed within tissues during an acute-phase reaction.

Currently available enteral nutrition preparations and solutions of vitamins and trace elements for PN solutions usually contain micronutrients in amounts recommended for healthy adults (RDA, recommended daily allowances). These quantities, however, do not necessarily meet

the altered nutritional requirements that may be sometimes increased or potentially reduced for acutely ill patients with AKI. Thus extra supplementations may become necessary for several vitamins and trace elements in addition to the amounts that are provided by enteral or PN (see next). One should differentiate “replacement,” that is, providing the daily requirement of a nutrient, which may be altered in a disease state, from “supplementation,” where higher, even pharmacologic, amounts of nutrients are provided to induce defined effects (referred to as “pharmaconutrition”). Pharmaconutrition may include provision of combinations of various antioxidants [116].

Several micronutrients are components of the antioxidative defense system of the body. In patients with AKI, an increase in oxidative stress and severe depression of the antioxidative system have been reported that can be more pronounced than in other acute disease states [117]. Reactive oxygen species (ROS) are involved in tissue (and kidney) injury in various clinical contexts, and adequate replacement or even supplementation of micronutrients should deserve much closer attention that has previously been displayed [40].

### Water-soluble vitamins

Plasma concentrations of several water-soluble vitamins are decreased in patients with AKI [111]. This is also observed in many other critically ill patients without AKI. A contributing factor in patients on RRT is the loss associated with extracorporeal therapy, as was shown for thiamine, vitamin C, folic acid, and pyridoxine [118–121]. Due to increased losses from RRT and the potentially increased metabolic requirements in acute disease states, it is recommended that higher amounts of water-soluble vitamins provided to acutely ill patients with AKI-2–3 [14,76].

An example is thiamine, where more than the recommended daily intake for healthy subjects may be removed by RRT [118]. Severe deficiency states of thiamine associated with symptoms such as lactic acidosis, cardiac failure, and variable neuropsychiatric symptoms have been observed in patients with AKI and CKDs [122]. The recommended amount of 3 mg/d of thiamine for healthy subjects is absolutely inadequate to both replete the deficiency state and to cover ongoing increased requirements in patients with AKI-3.

Vitamin C levels are also decreased in patients with severely ill AKI-2–3 [111]. Losses of vitamin C up to 830-mg vitamin C in a patient receiving 2 g of vitamin C have been reported [123]. The requirements for this vitamin are also higher in patients with AKI than the recommended intake for healthy adults of 50 mg/d. Care should be observed with supplementation since

vitamin C is a precursor of oxalic acid and excess intake can cause secondary oxalosis. Many cases of vitamin C–induced AKI have been reported [124]. On the other hand, in some recent studies using much higher doses of vitamin C in critically ill patients, adverse renal events have not been observed [125]. Thus the optimal intake of vitamin C is subject to much controversy and remains to be defined [123].

### Lipid-soluble vitamins

In patients with AKI-2–3, plasma vitamin K is normal, and plasma levels of the other lipid-soluble vitamins A, E, and D are reduced [126]. There are no RRT-associated losses for these vitamins. Vitamin E is an essential component of the antioxidative defense system. In various experimental models, vitamin E can prevent the development of renal injury. In combination with vitamin C, vitamin E supplementation reduced the risk of developing organ dysfunction in critically ill patients who did not necessarily have AKI [127].

AKI is associated with a profound vitamin D deficiency. There is impaired conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D (calcitriol), and hyperparathyroidism [126,128]. Plasma concentrations of 25- and 1,25-hydroxyvitamin D and calcium are decreased, and parathyroid hormone and FGF-23 are increased [129]. Moreover, vitamin D deficiency increases the risk of AKI [130]. On the other hand, overcorrection of vitamin D deficiency may cause AKI [131]. Vitamin D deficiency and hyperparathyroidism are present in many critically ill patients [132]. However, plasma concentration of 1,25-hydroxyvitamin D is directly correlated with renal function in these patients [133].

Beyond its effect on mineral metabolism, the steroid hormone vitamin D exerts several pleiotropic effects, for example, on immune function, intestinal mucosal integrity, myocardial performance, and glucose metabolism. The optimal dose of vitamin D for patients with AKI and which forms of vitamin D are preferable for supplementation—native vitamin D<sub>3</sub>, 25-hydroxycholecalciferol, calcitriol, or other vitamin D analogs—remain unknown. An ongoing study should shed more insight into the distorted vitamin D/mineral metabolism in patients with AKI and help to define the optimal vitamin D intake [134].

Some precaution should be taken with vitamin A supplementation in AKI patients and especially in infants. In experimental AKI, release of retinol and retinol-binding protein from the liver is increased [135]. In a study of 19 pediatric patients developing AKI after hematopoietic stem cell transplantation who required RRT, 17 displayed elevated vitamin A plasma levels during standard supplementation and showed

potential (albeit poorly defined) symptoms of hypervitaminosis A [136].

### Trace elements

A broad range of alterations in plasma trace element concentrations have been described in critically ill patients with AKI-2–3 with some trace elements decreased (selenium, zinc) and some increased (copper, cobalt, molybdenum) [111,113]. However, it is difficult to differentiate whether disorders in trace element metabolism are caused by renal dysfunction, by the acute disease state, and/or by inflammation.

Decreased plasma concentrations of several trace elements (e.g., selenium, zinc, or iron) in patients with AKI may be, in part, an expression of the acute-phase reaction and may not necessarily reflect a deficiency state but rather altered compartmental (tissue) distribution.

Because of the high protein binding of trace elements, their losses during RRT are usually low but may increase when albumin loss is increased, such as by using dialyzer membranes with higher molecular weight pore size cutoffs and/or a high transmembrane pressure [137,138].

Plasma selenium levels may be severely depressed in patients with AKI [113]. Losses are low during intermittent HD, but during CRRT, selenium elimination can be greater than the RDA. In patients undergoing maintenance HD therapy, selenium supplementation of 300 µg after each HD session improved the antioxidative defense system [138]. Several intervention studies have been performed administering selenium to critically ill patients. The selenium dose in many studies was clearly pharmacologic (up to 2000 µg/d) that cannot necessarily be regarded as safe in renal failure patients. In a large RCT, in critically ill patients, sodium selenite (1000-µg bolus and 1000 µg/d) reduced the number of RRT-free days but had no effect on mortality [139]. High-dose intravenous selenium is no longer recommended in critically ill patients [11].

Zinc is also considered to be an important nutrient in critically ill patients, many of whom have decreased plasma concentrations. Zinc is involved in immune function, the acute-phase reaction, antioxidative defense mechanisms, glucose homeostasis, and wound healing and may have renal protective potential [41]. No clinically significant losses of zinc occur during RRT [118].

Due to its active oxidant effects, iron can promote tissue injury and contribute to the development of AKI [140,141]. In animal experiments, interventions to limit iron availability (e.g., by providing hepcidin) can prevent AKI [142]. However, in a large RCT of intravenous iron

treatment for the anemia of the critically ill, the incidence of AKI was not increased [143].

Caution should be observed when infusing AKI patients with high-dose supplements of trace elements. Parenteral infusion of trace elements into AKI patients circumvents both regulatory elements of trace element homeostasis: intestinal absorption and renal excretion so the risk of inducing an overdose with toxicity may be higher than in other patient groups. Standard infusion solutions and dialysate itself may be contaminated with several trace elements, such as manganese, zinc, copper, or chromium [112,118]. In the absence of specific studies of micronutrient requirements in AKI, a standard intake of RDA is recommended for patients with AKI as it is for other critically ill patients [14].

### Other electrolytes

Derangements in electrolyte balance in patients with AKI can be affected by a broad spectrum of factors. In addition to the type and degree of kidney dysfunction, these factors include the residual GFR, the underlying diseases, severity of hypercatabolism, type and intensity of RRT, medicinal drug therapy, and also the timing, type, and composition of nutritional support.

Electrolyte requirements not only vary considerably between patients but also can fundamentally change during the course of the disease. In nonoliguric patients, subjects on CRRT and patients who are in the polyuric phase of AKI, electrolyte requirements can be considerably increased. Thus even more than other substrates, electrolyte requirements should be evaluated in each individual AKI patient on a day-to-day basis, and intakes may need to be adjusted frequently.

It should be noted that many electrolyte derangements, and especially hypokalemia, hypophosphatemia, and hypomagnesemia, increase the risk of developing organ dysfunction, including AKI. Thus avoidance of electrolyte derangements (for instance, as a result of refeeding syndrome) must constitute a primary focus of the metabolic care of patients with or at risk for AKI (vide supra).

**Potassium:** AKI often is complicated by hyperkalemia because of impaired urinary excretion, increased potassium release during protein hypercatabolism, and altered distribution between intra- and extracellular spaces caused by the uremic state per se, by acidosis, and by drugs such as digitalis glycosides or beta-antagonists. Therapy of metabolic acidosis may decrease the requirement of RRT by reducing plasma potassium concentrations [29]. However, many patients with AKI may present with decreased serum potassium. When correcting hypokalemia in an

AKI patient, potassium repletion must be performed at a lower rate than in nonrenal patients to avoid inducing overshoot hyperkalemia.

**Phosphorus:** In contrast to CKD, hyperphosphatemia usually is of minor relevance in patients with AKI. Nevertheless, hyperphosphatemia per se can cause AKI by precipitation of calcium phosphate crystals within the kidneys (acute phosphate nephropathy). This can be due either to release of phosphate from cells (such as in tumor lysis syndrome) or by excess intake of phosphate (e.g., by phosphate-rich enemas) [144].

In patients receiving RRT, hypophosphatemia is much more relevant and common than hyperphosphatemia. Inadequate intake, internal redistribution due to inflammation, and increased losses, mainly through RRT (especially with phosphate-free RRT), can contribute to decreased plasma phosphate concentrations. Hypophosphatemia is associated with many side effects, including respiratory failure, difficulty weaning from mechanical ventilation, decreased cardiac contractility, and increased risk of infections, attention should be paid to providing adequate phosphate supplementation and the use of phosphate-containing replacement fluids [145,146].

Hypophosphatemia can be a consequence of the refeeding syndrome [55]. Since patients with AKI may be given nutritional support that is phosphate free, plasma phosphate can fall precipitously particularly when such nutritional therapy is given to subjects with severe malnutrition.

**Calcium:** The majority of patients with AKI-2–3 are hypocalcemic with a reduction of both protein-bound and ionized fractions [147]. In most critically ill patients, the degree of hypocalcemia correlates with the severity of illness. The causes of hypocalcemia are manifold and can include hypoalbuminemia, hyperphosphatemia, citrate anticoagulation, the impaired formation of 1–25 (OH)<sub>2</sub> vitamin D<sub>3</sub> with reduced intestinal calcium absorption, and, potentially, skeletal resistance to parathyroid hormone. During citrate anticoagulation hypocalcemia may develop due to the chelation of calcium by citrate; parathyroid hormone secretion may increase if calcium is not adequately replaced [148].

Hypercalcemia may be caused by high dialysate calcium concentrations, immobilization, acidosis, and/or hyperparathyroidism. In AKI caused by rhabdomyolysis, persistent elevations of serum calcitriol may result in a rebound hypercalcemia during the diuretic phase. Acute hypercalcemia per se can cause AKI by inducing acute nephrocalcinosis, arterial calcifications, and interstitial nephritis.

**Magnesium:** Hypomagnesemia occurs frequently in patients with AKI and may be caused by the acute illness per se, the use of magnesium-free replacement fluids for hemofiltration, and citrate anticoagulation,

and increased urinary magnesium losses that may occur during the diuretic phase of AKI and after renal transplantation. Several nephrotoxic drugs, such as cisplatin, aminoglycosides, and amphotericin B, may cause renal magnesium wasting [149].

Magnesium deficiency may aggravate renal tissue injury. In contrast, magnesium repletion may be protective, especially after exposure to nephrotoxins [150]. Sometimes potassium depletion may occur with hypomagnesemia. In these circumstances the hypokalemia can only be corrected when magnesium and potassium are replenished [151].

Clinically important elevations of serum magnesium are rare in patients with AKI. Symptomatic hypermagnesemia can develop with high magnesium intakes given with oral, enteral, or PN.

### **Effect of renal replacement therapy on body metabolism and nutrient balances**

The effect of various modalities of RRTs on body metabolism and nutrient balances are manifold and are mediated by treatment-associated nutrient losses, bioincompatibility of dialyzer membranes and tubing, activation of various signaling cascade systems, and the release of cytokines, which ultimately induce an inflammatory reaction [113] (Table 35.5).

### **Intermittent hemodialysis**

Most patients with community- and hospital-acquired AKI are treated with conventional intermittent HD. During HD, several water-soluble molecules, such as amino acids, water-soluble vitamins, and carnitine, are lost (vide supra) [120]. Amino acid loss accounts for approximately 2 g/h dialysis session.

Protein catabolism is stimulated not only because of these amino acid losses but also by activation of protein breakdown. Various inflammatory markers rise during HD and this rise—along with the stimulation of protein catabolism—persists until several hours after end of HD [152,153]. Moreover, HD induces an oxidative stress and generation of ROS that is augmented by the associated losses of nutritional antioxidants [154].

In sharp contrast to CKD patients, patients with AKI are at risk of developing hypophosphatemia during HD, and this is associated with impaired prognosis [155].

### **Continuous renal replacement therapy**

In many critical care units, CRRT is the preferred modality of RRT for treatment of patients with AKI.

TABLE 35.5 Metabolic effects of renal replacement therapy in acute kidney injury.

**Intermittent HD**

- Loss of water-soluble molecules
  - Amino acids
  - Water-soluble vitamins
  - L-Carnitine etc.
- Activation of protein catabolism
  - Loss of amino acids
  - Loss of proteins and blood
  - Induction of inflammation/cytokine release (TNF- $\alpha$  etc.)
- Inhibition of protein synthesis
- Increase in ROS-production

**CRRT**

- Heat loss
- Excessive load of substrates (lactate, citrate, glucose, etc.)
- Loss of nutrients (amino acids, vitamins, selenium, etc.)
- Loss of electrolytes (phosphate, magnesium)
- Elimination of peptides and proteins (hormones, mediators, albumin)
- Consequences of bioincompatibility (induction/activation of mediator-cascades, of an inflammatory reaction, stimulation of protein catabolism)

CRRT, Continuous renal replacement therapy; HD, hemodialysis; ROS, reactive oxygen species; TNF- $\alpha$ , tumor necrosis factor- $\alpha$ .

Because of the continuous mode of therapy and associated high fluid turnover of up to 60 L/day or more, this treatment modality may induce a broad pattern of metabolic consequences (Table 35.5).

A relevant side effect of CRRT is the elimination of small- and medium-sized molecules. These losses are extremely variable depending on the mode, membranes used, dose, duration of the therapy, and the type of anticoagulation, so approximate values can only be given.

In the case of most amino acids, the sieving coefficient approaches 1.0, so the loss of amino acids can be estimated from the volume of the filtrate and the average plasma concentrations. However, because of the electric charges of several amino acids and the characteristics of the filtration membrane, the sieving coefficient can also exceed 1.0, such as for glutamine and arginine, which are the amino acids with the highest losses during CRRT [156].

Usually, amino acid losses amount to approximately 0.2 g/L filtrate. Depending on the filtered volume, this can account for a total loss of 5–15 g amino acids per day, representing about 10%–15% of the amino acid intake. Amino acid losses during continuous hemofiltration (CVVH) and continuous HD (CVVHD) are of a similar magnitude [156,157]. In a more recent study, amino acid losses of 5.13 g were measured during one HD session, losses of 8.21 g during 12 hours of slow efficiency dialysis, and 18.7 g during 24 hours of CRRT [113].

What often is ignored is the fact that, depending on the type of therapy, the dialyzer membrane material and the effective transmembrane pressure can contribute to additional protein losses of up to 20 g/day.

Water-soluble vitamins, such as thiamine, folic acid, vitamin B6, and vitamin C, are also eliminated during CRRT, and an intake above the RDA is required to maintain plasma concentrations of these vitamins in patients with AKI (see previously).

Because of the high protein binding, losses of trace elements during RRT usually are low but can become clinically important with modern high-flux membranes, if high transmembrane pressures are used, or if there is a leak of albumin and other proteins. Selenium losses by convective transport during CRRT can be higher than the RDA [118] (see previously).

Glucose balance during CRRT is dependent on the glucose concentration of the replacement fluid. Solutions designed for peritoneal dialysis should not be used for CRRT, because they promote excessive glucose uptake. Dialysate glucose concentrations should range between 1 g and 2 g/dL to maintain a zero glucose balance.

Uptake of lactate, the organic anion present in some replacement fluids during CRRT, can be considerable and within the range of endogenous lactate turnover. During disease states associated with increased lactate formation (such as cardiogenic shock) or decreased lactate clearance (liver insufficiency), bicarbonate-based replacement fluids should be used to prevent excessive rises in plasma lactate concentrations.

Recently, in several countries, citrate anticoagulation has become standard for RRT of AKI patients. Since citrate is predominantly catabolized in the liver, liver dysfunction can result in decreased citrate clearance, and citrate utilization must be monitored, for example, by monitoring the total: ionized serum calcium ratio. Citrate also serves as energy source and an additional

energy intake of up to 400 kcal/d is associated with the use of citrate anticoagulation [77].

Special attention should be paid to electrolyte balances during CRRT. Depending on the filtration rate and duration of CRRT, the risk of inducing hypokalemia and especially hypophosphatemia can be very high (see previously). Even at low-intensity CRRT (e.g., a filtration rate of 25 mL/kg/h), 54% of patients developed hypophosphatemia and 24.5% developed hypokalemia [158].

Patients with AKI treated by RRT should be given also be given intravenous nutrition at least during the extracorporeal therapy. The endogenous clearance of amino acids is in the range of 80–1800 mL/min and thus exceeds dialytic clearance by 10–100 times. Nutritional infusion during RRT results in minimal increases in plasma amino acid concentrations, and therefore only a small fraction, about 10% of the amino acids infused, will be removed by the RRT, in addition to the basal amino acid losses that would occur without the amino acid infusion.

### **The role of nutritional status and nutrient supply on clinical outcome**

As in other acute and chronic diseases in patients with AKI, a poor nutritional state is associated with an increased risk of complications and an impaired prognosis [159]. In a large study, preexisting severe malnutrition is present in 42% of patients with AKI and is associated with such complications as sepsis and septic shock, hemorrhage, cardiac arrhythmias, cardiogenic shock and respiratory failure,

prolonged hospital stay, and increased hospital mortality [160]. Both sarcopenia and decreased muscle strength are each associated with a poor outcome [161].

Obesity, on the other hand, increases the risk of developing AKI [162]. However, a high body mass index confers a protective role and improves prognosis in patients with AKI (obesity paradox) [162,163]. Since obesity is often associated with deficiency states of various nutrients and with protein wasting (such as “sarcopenic obesity”), nutrition support should not be withheld in overweight or obese patients with AKI.

## **Practical issues concerning clinical nutrition in patients with AKI-3 requiring RRT**

### **General considerations**

The practice of nutritional support in AKI patients is not fundamentally different from that in patients without renal dysfunction. However, as detailed previously, the nutritional regimen should be adapted to the altered metabolism and nutrient requirements and nutrition must be coordinated with RRT.

The optimal intake of nutrients in patients with AKI is influenced more by the nature of the illness causing AKI, the extent of catabolism, and the type and frequency of RRT rather than renal dysfunction per se. In most clinical situations, daily requirements will exceed the minimal intake recommended for stable nondialyzed CKD patients or the RDA for normal subjects.

Nutrient requirements are summarized in Table 35.6. It must be stressed that these are approximate values

TABLE 35.6 Nutrient requirements in acute kidney injury-3 requiring renal replacement therapy (RRT)<sup>a</sup>.

<b>Energy intake</b>	20–25 (max. 30)	kcal/kg/d
Glucose	3–4	g/kg/d
Lipids	0.8–1.2	g/kg/d
<b>Amino acids/protein</b>		
+ RRT	1.2–1.5	g/kg/d
+ Hypercatabolism	(Max. 1.7)	g/kg/d
<b>Vitamins</b>	(Combination products proving RDA)	
Water soluble		2 × RDA/d
Lipid soluble		1–2 × RDA/d (higher for vitamin D?)
<b>Trace elements</b>	(Combination products proving RDA)	
		1 × RDA/d
<b>Electrolytes</b>	(Requirements must be assessed individually)	
	(Beware of: hypokalemia and hypophosphatemia)	

<sup>a</sup>Requirements differ between individual patients and may vary considerably in the same patient during the course of the disease.  
RDA, Recommended dietary allowances.

only which are not based on high-quality RCTs but on expert opinion (i.e., “weak evidence, low level of recommendation”). Patients with AKI present an extremely heterogeneous group of subjects with widely differing nutrient requirements, and these needs may differ considerably between individual patients and may vary greatly during the course of disease in the same patient. So individual daily assessments of nutrient requirements are mandatory.

### Oral nutrition in patients with acute kidney injury

Oral nutrition should be encouraged whenever possible, and this is often feasible in noncritically ill, non-catabolic patients presenting with AKI as mono-organ dysfunction who are mostly cared for on open wards.

The dietary goals in these stable patients are similar to those for CKD patients (see the chapter on nutrition in HD). In patients not requiring RRT the diet should start with about 0.4 g (high-quality) protein/kg BW/d and be gradually increased to about 1.0 g/kg BW/d as long as the SUN remains below 80 mg/dL. In patients requiring RRT, protein intake should be increased to 1.2–1.4 g/kg BW/d. Patients should receive an adequate intake of water-soluble vitamins and vitamin D, and electrolyte balance must be maintained.

In patients who do not eat adequately the provision of liquid diets or ONS may be used to improve total nutrient intake. Commercially available diets designed for patients with CKD can be used for this purpose (see next). For patients with CKD-3–5, protein and electrolyte restricted diets are available. These diets with a moderately increased amount of protein but with lower electrolyte content (i.e., potassium, magnesium, and phosphate restriction) can be used for patients requiring RRT. Some of these diets have other nutrients added, such as carnitine, and are enriched with various flavors to improve the taste.

During the dialysis session, patients can be encouraged to eat or to drink liquid diets or supplements (intradialytic enteral nutrition) (see next).

### Enteral nutrition

Enteral nutrition is also the preferred route of nutritional support for AKI patients who are unable to eat foods. The advantages of enteral nutrition are manifold and include the support of intestinal defense functions against translocation of bacteria, the support of the enteric immune system, and, thus ultimately, the reduction in infectious complications.

Enteral nutrition may confer an additional advantage with regard to recovery of renal function. In experimental AKI, enteral nutrition as compared to PN has been shown to accelerate recovery of renal function [164]. In clinical studies on outcome in AKI patients requiring RRT, enteral nutrition was associated with an improved survival [165].

In AKI patients the effect of acute kidney dysfunction on the gastrointestinal function, and especially on gastrointestinal motility, is of crucial importance with regard to the ability to provide enteral nutrition. A broad spectrum of gastrointestinal abnormalities have been described in uremia, but unfortunately, few studies have examined these disorders in AKI. It is known that AKI gastric emptying is retarded and intestinal transit time is prolonged [166].

Acute disease states and postoperative and post-traumatic conditions are also associated with impaired motility in various segments of the gastrointestinal tract. In the critical care setting, these disorders can be augmented by an increase in intraabdominal pressure and by various medicines. Sedation therapy, analgesia using opiates, catecholamines, and other medicines may contribute to impaired intestinal motility [167].

Thus, in many patients with AKI, the acute kidney dysfunction in combination with these various other factors can profoundly impair gastrointestinal motility and compromise one's ability to attain dietary goals with enteral nutrition. Many patients with AKI will require drugs that enhance motility, both at the level of the stomach and the small and large intestines. Again, this aspect of gastrointestinal function has not been specifically investigated in patients with different stages of AKI. In critically ill patients, erythromycin at a low dose (1–2 mg/kg BW up to thrice daily) may effectively stimulate motility both at the gastric and the intestinal levels. An alternative approach is to use a combination of metoclopramide (for promotion of gastric emptying) and parasympathomimetics such as neostigmine (for stimulation of intestinal motility). Several other drugs currently are under investigation [11,167]. Prokinetic drugs should be given early, if not prophylactically, to facilitate the early use of enteral nutrition.

If it is not possible to adequately stimulate motility with these medicines, the placement of a postpyloric jejunal tube should be considered. With this approach, it is often possible to achieve the nutritional goals. However, there still remain a considerable number of patients who cannot be fed per the enteral route alone and who will require supplemental or even total PN (see next).

## Enteral diets for the patient with acute kidney injury

There are no commercial diets that have been specifically developed for AKI patients. Three types of diets have been used for this patient group:

1. Elemental amino acid diets (mostly powder): These diets were originally designed for supplementation of low-protein diets with essential amino acids for stable CKD patients. They should not be used for AKI patients because these diets are incomplete and inadequate for acutely ill patients who have increased nutrient requirements.
2. Standard liquid diets that are used for nonuremic patients.
3. Liquid formula diets that (1) have a reduced protein and electrolyte content and are adapted to the needs of CKD-3–5 patients who do not require RRT or (2) that have a moderately increased in protein content, are reduced in electrolytes (potassium, phosphate, magnesium, sodium) designed for patients on RRT and that may contain other nutrients, such as carnitine.

In general, the standard diets recommended for other critically ill patients are also recommended for critically ill patients with AKI [13,14]. It should be noted that in acutely ill patients on RRT, hyperkalemia or hyperphosphatemia are rarely clinically relevant problems; so the use of electrolyte restricted diets usually is not mandatory. These diets contain the RDA of micronutrients only for healthy subjects, and care should be taken that water-soluble vitamins, vitamin D and possibly also selenium and zinc, are supplemented adequately.

**Immunonutrition:** Whether the addition to enteral nutrition preparations of such potential immunomodulating substrates, as fish oil, antioxidants, nucleotides, or glutamine, has advantages for patients with AKI remains unknown. The main indications for the use of these immunomodulating supplements diets are perioperative situations, but they are not recommended for critically ill patients with a high severity of illness (i.e., APACHE II Score >25) [11,12].

Enteral diets should contain dietary fiber (water soluble or insoluble). This is not recommended so much to reduce uremic toxicity and the inflammatory state, as has been suggested for CKD patients, but for the metabolic effects, the protective actions of short-chain fatty acids on the colon, and the promotion of intestinal motility [168].

**Feeding tubes:** Fine pore nasogastric feeding tubes are a standard feature of enteral feeding. Because feeding tubes are often used for extended periods of time, these tubes should be made of tissue-friendly material,

such as silicone or polyurethane, and not of polyvinylchloride that can cause ulcerations in the upper digestive tract.

As discussed previously, postpyloric feeding tubes should be considered in patients with severe gastrointestinal intolerance and high gastric residual volumes. The tube tip should be positioned well after the ligament of Treitz; the end of the feeding tube should not be positioned in the duodenum. Postpyloric tubes should have a second lumen for gastric decompression and administration of medicines into the stomach. Self-advancing (in part electromagnetically visualized) tubes are available that can be positioned within an acceptable time frame (with some experience within less than 20 minutes) and without the need for endoscopy [169].

Enteral nutrition should be started early; that is, within 24 hours after admission, at a low rate of infusion and gradually increased over 5–7 days [43].

**Stress ulcer prophylaxis:** Enteral nutrition confers some protection against the development of stress ulcers and gastric bleeding. Patients with AKI usually are high-risk patients for gastric ulcers; hence in many AKI patients, ulcer prophylaxis, preferably with proton pump inhibitors, will be necessary.

## Clinical studies of enteral nutrition in patients with acute kidney injury

In sharp contrast to the worldwide daily routine practice of enteral nutrition in patients with AKI, very few systematic studies have been performed on these patients. There is only one major study evaluating enteral nutrition in AKI. This was more of a feasibility study that compared patients without AKI (control group) to patients with AKI who were or were not receiving RRT [170]. As compared to patients without renal dysfunction, patients with AKI had higher gastric residual volumes, and there was a trend to more frequent withdrawal of enteral nutrition due to complications. A standard enteral formula was used, which was partially adapted for CKD patients. But because of lack of randomization, no conclusions can be drawn concerning the advantages of such adapted diets. In general, the enteral nutrition was well tolerated, and the rate of nutrient delivery was similar comparable among all groups.

## Parenteral nutrition in acute kidney injury

Historically, most studies of nutritional support in AKI patients were performed using PN. However, because of its well-defined advantages, enteral

nutrition should be preferred whenever possible. Nevertheless, for many reasons, as discussed previously, in a considerable fraction of AKI patients, it may not be feasible to provide adequate nutrition enterally and supplemental or total PN may be necessary. However, even when PN becomes mandatory, a minimal amount of enteral nutrition (trophic or trickle nutrition) should be attempted whenever possible to support intestinal function.

In general, it is recommended that PN be started not earlier than 3–7 days after admission [12]. However, in patients with AKI and malnutrition and in patients requiring RRT, especially for those undergoing intensive dialysis treatment, which is associated with larger nutrient losses, it may be inappropriate to delay PN, and it should be started earlier. The progressive increase in PN to the desired levels should be slower than has been recommended in the past. The final infusion volume and nutritional goals should not be attained until 5–7 days after initiation of PN [11].

It should be noted that the nutrients infused are not toxic. Many of the negative side effects associated with the PN are due to inadequate planning, for example, excessive energy intake, solutions lacking one or more key nutrients, too rapid an increase in the infusion rate, too high an infusion rate, or insufficient monitoring (e.g., leading to hyperglycemia) rather than to the parenteral route of nutrient supply per se. Properly performed PN is not associated with a higher rate of complications than enteral nutrition [171].

### Components of the parenteral nutrition solution

**Amino acid solutions:** In the early days of nutritional support of AKI patients, amino acid solutions containing only essential amino acids were used. This practice was based on the concept of diets providing very low amounts of protein diet or essential amino acids for the treatment of CKD patients. These amino acid solutions are incomplete, have an unbalanced composition, and in large amounts (i.e., >40 g or essential amino acids per day with no nonessential amino acids) may cause such life-threatening complications as hyperammonemic coma. They have been abandoned in favor of solutions containing essential and nonessential amino acids.

The standard complete amino acid solutions that are used for patients without renal dysfunction are recommended for patients with AKI. In several countries, specific amino acid solutions adapted to the metabolic alterations of AKI are also available [66]. These solutions may contain different combinations of essential and nonessential amino acids and higher concentrations of conditionally essential amino acids. Some of

these solutions are supplemented with a tyrosine containing dipeptide, such as glycyl-tyrosine, as a source of this conditionally essential amino acid in uremia. The advantage of the dipeptide is its greater solubility; tyrosine has a low solubility in water and cannot be added to an amino acid solution as the free amino acid in adequate amounts [81]. Beyond normalizing the plasma amino acid pattern and improving nitrogen balance, whether these modified solutions can improve clinical outcome remains to be shown. In general, disease-specific amino acid solutions are not recommended for the nutritional support of critically ill patients [11,12].

In animal experiments, it has been demonstrated that amino acids imbalances exert negative effects not only on protein metabolism but also on more complex cellular functions such as signaling pathways and gene activation [172]. These new insights may potentially stimulate a renewed interest in disease-modified amino acid solutions.

For the hypercatabolic critically ill patient glutamine has been regarded as a conditionally essential amino acid. An intake 0.3 g glutamine/kg BW/d has been recommended for these patients. Since free glutamine is not stable in aqueous solutions, glutamine-containing dipeptides (such as alanyl-glutamine) are used as the glutamine source in PN. Several recent studies, however, have not demonstrated beneficial effects of glutamine supplementation [173]. In a secondary analysis of a large RCT, patients with renal injury who were randomized to receive glutamine had a higher mortality [65]. In recent recommendations, renal failure, as with hepatic failure, is considered to be a contraindications for glutamine supplementation [11,12].

**Glucose:** Glucose should be the main energy substrate. In contrast to earlier recommendations, glucose intake must be restricted to 2 to a maximum of 4 g/kg BW/d. This is recommended because additional glucose above these doses may not be oxidized yielding energy but may be directed to lipogenesis with fatty infiltration of the liver. Higher glucose doses may also produce excessive carbon dioxide, promoting hypercapnia in patients with reduced pulmonary function and impair immunocompetence, thereby increasing the risk of infectious complications.

Glucose tolerance is decreased in AKI, and infusion of insulin is frequently necessary to prevent hyperglycemia, which presents not only a risk factor for complications (especially infections) but also for renal injury and other organ complications (vide supra). The therapeutic target during nutritional support in the critically ill is no longer normoglycemia, however. Plasma glucose levels should not exceed 180 mg/dL [12]. It should be noted that during PN, insulin requirements

are approximately 25% higher than during enteral nutrition. The amount of glucose infused and, hence, the risk of developing hyperglycemia can be reduced by limiting energy intake and providing a portion of the energy by lipid emulsions.

**Lipid emulsions:** The changes in lipid metabolism associated with AKI should not prevent the use of lipid emulsions, but the amount infused must be adjusted to the patient's capacity to clear and utilize lipids. Plasma triglyceride concentrations should be monitored regularly. Usually, 1 g fat/kg BW/day will not increase plasma triglycerides substantially.

Conventional lipid emulsions mostly contain plant oils (soy oil, safflower oil) with a high content of polyunsaturated omega-6 fatty acids (PUFA). PUFA-derived eicosanoids may exert proinflammatory, vasoconstrictor, and thrombocyte proaggregatory effects. There is an ongoing discussion as to whether lipid emulsions with a lower content of these PUFA (e.g., partly replacing soybean oil with olive oil, fish oil, or medium-chain triglycerides) are preferable for PN in critically ill patients [174]. Alternative oils, and especially fish oil—containing omega-3 fatty acids, can serve as precursors for potentially more beneficial eicosanoids and—importantly—for a novel class of lipid mediators, protectins, and resolvins, which are essential for the resolution of an inflammatory process [175]. In the experimental situation, fish oil can exert nephroprotective actions and prolong survival [54]. Again, systematic clinical studies in patients with AKI are not available.

Nevertheless, in several countries, such modified lipid emulsions containing a variable mixture of various oils (soy oil, coconut oil, olive oil, fish oil) have become available recently, and various international nutrition societies recommend the use of these modified lipids in PN [174].

**Micronutrients:** PN solutions must be complete and thus must contain all essential micronutrients. Multivitamin and multitrace element preparations are available that can be added directly to the nutrition solution. As discussed previously, double amounts of water-soluble vitamins should be provided. If higher selenium supplements are to be infused, an extra infusion should be employed for selenium, because of potential nutrient interactions (e.g., between vitamin C and selenium). Increased amounts of vitamin D or its analogs also should be provided to cover the greater requirement for this vitamin.

**Electrolytes:** Electrolyte requirements must be carefully assessed on a day-to-day basis and must be adapted individually. Electrolytes to handle basal requirements can be added to the nutrition solution. More pronounced electrolyte deficits may be covered with separate infusions.

**PN solutions:** The use of total nutritional admixtures (all-in-one solutions) has become standard

worldwide. These solutions either are standard products provided by the pharmaceutical industry, usually in multichamber bags (MCBs) with a long shelf life or custom-made by the hospital pharmacy or compounding companies. The use of MCBs helps to reduce costs and also the risk of infection [176]. Usually, these MCBs contain basic solutions containing the three macronutrients, glucose, amino acids, and a lipid emulsion, and variable amounts of electrolytes. Water- and lipid-soluble vitamins, trace elements, and other electrolytes are added as required before use.

When enteral nutrition is not possible, PN should also be started early in patients with AKI. To ensure maximal nutrient utilization and to avoid metabolic derangements, the infusion should be started at a low rate (see previously), providing about 30% of requirements initially and gradually increasing over several days. The nutrition solution should be infused continuously over 24 hours to ensure optimal substrate utilization and to avoid marked changes in substrate concentrations in patients who may have decreased ability to utilize the nutrients.

### Clinical studies on parenteral nutrition in patients with acute kidney injury

As with enteral nutrition, there are a distressingly low number of systematic studies evaluating PN in patients with AKI. Several older studies assessed isolated aspects of intravenous nutrition, such as the optimal types of amino acids to be infused solution (e.g., only essential amino acids vs essential and nonessential amino acids), the severity of protein catabolism, the optimal intake of amino acids and protein, but systematic outcome studies have not been performed during the last 25 years.

It should be noted that most of these older studies do not meet current standards and practice of nutritional therapy in acutely ill patients with respect to the type and quantity of the amino acids infused, the energy intake, or the overall composition of the nutrition solution. All studies were markedly underpowered to assess hard endpoints such as survival or recovery of renal function. Moreover, in some of these studies, the control group received no nutrition at all or were given glucose alone.

Some of these prospective randomized studies are shortly summarized.

Abel et al. randomly assigned 53 patients with AKI to receive either a mean of 16 g/d of essential amino acids with hypertonic glucose or hypertonic glucose alone [177]. The survival rate was greater in patients receiving essential amino acids and this was especially seen in the sicker patients with serious complications and who required dialysis therapy.

Similarly, Feinstein et al. assigned 30 patients with AKI to three groups, to receive glucose alone, glucose and 21 g/d of essential amino acids, or glucose and 21 g/d essential plus 21 g/d nonessential amino acids [100]. In general, results were inconclusive, but there was a trend toward better nitrogen balance and clinical outcome in patients receiving more amino acids.

In a further prospective trial the same group of authors compared in an even smaller group of 13 AKI patients PN providing 21 g/d of essential amino acids with a solution with a higher amino acid intake (an amount of essential plus nonessential amino acids that was approximately equal to the urea nitrogen appearance rate) [178]. The purpose of this exploratory study was to examine the effect of these amino acid intakes on nitrogen balance in AKI patients. Nitrogen balance was not different and, as was expected in this small trial, recovery of renal function and mortality were comparable.

Some of the newer studies that have tried to assess the severity of protein catabolism and define protein and energy requirements in patients with AKI are described earlier.

In general, uncontrolled cohort studies (prospective or retrospective) support the view that an early high energy and protein intake is associated with improved survival [98,179–181]. This, however, is probably reflection of “reverse causality” since it is usually more difficult to infuse adequate amounts of nutrition into sicker patients. Prospective studies (usually subanalyses of larger trials) have all demonstrated that a slow buildup is associated with an improved outcome [44,64,182,183].

In conclusion, there are no recent systematic, randomized prospective trials of PN in AKI patients using current standards of nutritional support. Therefore no evidence-based recommendations based on randomized controlled clinical trials can be given for AKI patients. But recommendations can be made for AKI patients that are based on studies of acutely ill patients in general with some adaptations made for patients with AKI [13,14].

### **Intradialytic enteral or parenteral nutrition in patients with acute kidney injury**

Intradialytic oral or PN (IDPN) has been shown to revert the catabolic effects of an HD treatment into an anabolic condition in clinically stable chronic HD patients [184]. Several nutritional indices can be improved by using ONS or IDPN at least in chronic HD patients [185].

For AKI patients who are cared for on an open ward without adequate oral intake, IDPN may offer a possibility to improve total nutrient intake, not so

much to improve the patient's nutritional status but rather to prevent the further loss of lean body mass during the acute disease process. However, it must be noted that, again, no studies are available in this specific acutely ill patient group that examine the effects of this treatment.

### **Complications of nutritional support in patients with acute kidney injury**

Side effects and complications of nutritional support in patients with AKI are not fundamentally different from those in other patient groups. However, for reasons discussed previously, the risk for essentially all nutrition-associated complications is increased in the AKI patient.

Gastrointestinal side effects are more frequent, gastric residual volumes are increased, the general tolerance to enteral nutrition is decreased, and, thus, close monitoring of enteral nutrition therapy and the institution of measures to improve gastrointestinal motility and tolerance to enteral nutrition is mandatory.

Because of the compromised immune function in AKI, infectious complications originating from the central venous catheter are more frequent. RRT per se presents an additional risk factor for infection in AKI patients. Tolerance to excessive fluid volumes is impaired. Careful fluid balance must be observed, and excess infusion of fluid should be avoided. Overhydration has been recognized recently as an important factor associated with poor outcome [186]. In contrast to common thinking, overhydration also impairs renal function.

Obviously, electrolyte imbalances are frequent in AKI patients. It should be noted, however, that not only excess but also deficiencies of electrolytes, especially for phosphate and potassium, are often present in these patients. Metabolic complications frequently occur in patients with AKI because utilization of essentially all nutrients is altered or impaired. The risk for both hyperglycemia and hypertriglyceridemia is increased in AKI patients as compared to other patient groups. One reason for gradually increasing the infusion rate of the nutritional solution is to avoid many of the side effects and complications associated with nutritional support in AKI patients.

### **Monitoring nutritional support in patients with acute kidney injury**

Because of the limited tolerance to various nutrients and the high risk of inducing metabolic derangements in AKI patients, nutritional therapy requires a tighter

TABLE 35.7 A minimal suggested schedule for monitoring plasma or serum during nutritional support.

Variables	Patients who are metabolically	
	Unstable	Stable
Glucose, potassium	1–6 × daily	Daily
Phosphate	1–3 × daily	3 × weekly
Sodium, chloride	Daily	3 × weekly
Calcium, magnesium	Daily	3 × weekly
Osmolality	Daily	1 × weekly
SUN/SUN rise/day	Daily	3 × weekly
Triglycerides	Daily	2 × weekly
Blood gas analysis/pH	1–3 × daily	1 × weekly
Urea nitrogen appearance/estimate of protein catabolism	2 × weekly	1 × weekly
Ammonium	2 × weekly	1 × weekly
Transaminases + bilirubin	2 × weekly	1 × weekly

schedule of close monitoring than in other patient groups. Table 35.7 summarizes laboratory tests that are used to monitor nutrition support to avoid metabolic complications. The frequency of testing will depend on the metabolic stability of the patient. Concentrations of plasma glucose, potassium, and phosphate should be monitored repeatedly after initiating nutritional therapy.

**Glucose control:** As discussed earlier, hyperglycemia presents a risk factor for kidney dysfunction in acute disease states. On the other hand, AKI per se is associated with insulin resistance. Hence, glucose control by insulin infusion is mandatory in most acutely ill AKI patients. In contrast to earlier recommendations, however, glucose control should not be too tight and should not aim for normoglycemia. Rather the goal should be to maintain plasma glucose concentrations below 180 mg/dL. Optimally, an algorithm for glucose control should be followed.

**Triglycerides:** Due to the impairment of lipolysis and retarded plasma clearing capacity for triglycerides, adaptations to lipid infusion can become necessary. Simultaneous infusion of propofol, which is frequently used for sedation therapy and is a drug that is dissolved in a 10% lipid emulsion, can lead to increased plasma lipid levels. This should be considered when designing the nutritional regimen.

**Electrolyte balance:** It is a commonplace that AKI is associated with various electrolyte imbalances, and a close monitoring schedule is mandatory. Nevertheless, it again should be stressed that the risk of deficiency states is increased in AKI for some electrolytes, particularly potassium and phosphate.

## Epidemiology of stones

The field of kidney stone prevention is still in its infancy with a relative paucity of high-grade, evidence-based data suitable for inclusion in this chapter. Luckily, numerous studies regarding treatment and best outcomes are underway and robust, evidence-based data should become increasingly available [1]. Insights from genetics, understanding of microbiota, and an appreciation of the “exposome,” the accumulation of environmental exposures during a lifetime, are contributing to our understanding of kidney stone disease as a chronic metabolic condition marked by acute episodes [1].

Kidney stones are becoming more common and are associated with significant morbidity. The overall prevalence of kidney stones has increased in the United States from 3.8% of the population in 1976–80 to 8.8% of the population in 2007–10 based on NHANES data [2]. Non-Hispanic white men have the highest prevalence of stones, followed by Hispanic men, non-Hispanic white women, and Hispanic women. Non-Hispanic Black men and women have the lowest prevalence of stones at 4.8% and 4.2%, respectively. The prevalence of kidney stones increases with age: 16% of men and 7% of women over the age of 70 had passed at least one stone in their lifetime. The prevalence of kidney stones increased in men until the age of 65, and in women until the age of 70 [3]. In a group of calcium oxalate stone formers, the prevalence of diabetes mellitus, hypertension, and increasing BMI, all risk factors for stone disease, increases from age 18 to 69 prior to declining in those aged 70 or more [4].

## Risk factors

Bladder stones, primarily composed of ammonium acid urate, were historically more common in children in resource-poor, predominantly agricultural areas. As diets became richer in animal products, the incidence of bladder stones decreased, perhaps due to the impact of greater intake of phosphorus in the diet [5]. Bladder stones are now very uncommon in the United States except in instances of lower urinary tract obstruction due to prostatic hypertrophy, leading to, most often, uric acid stones.

Upper urinary tract stones (in the kidney or ureter) may be considered a disease of relative prosperity. The incidence of stones decreased during both world wars in Europe and Japan and increased after the wars ended. It is speculated that a return to a more animal protein-rich diet may explain the association [5].

In the current day, it is well understood that nutritional factors play a role in the development of kidney stones. There is a wealth of dietary data from prospective population studies which has helped elucidate which dietary habits increase risk of an incident kidney stone. The Health Professionals Follow-up Study (HPFS) includes over 45,000 men ages 40–75, while the Nurses’ Health Study (NHS) I and II include roughly 100,000 women in each study, aged 30–55, and 25–42, respectively. Information on diet, medical history, and medications was collected at study initiation. Those with a prior history of kidney stones were excluded from data analysis.

\*We are indebted to Dr. Marvin Grieff and Dr. David Bushinsky who wrote the previous edition of this chapter.

Putative dietary promoters of calcium-containing stones include high sodium intake (seen in women, not men), high protein intake (seen in men but not women), and high sucrose intake (seen in women, not men). Putative dietary inhibitors of calcium-containing stones include higher potassium intake (both men and women), high magnesium intake, high fiber intake, and high vitamin B6 intake (in women, not men) [6]. The reasons why some of these dietary factors are significant in one sex and not the other are not known.

Higher fluid intake and a diet more consistent with the Dietary Approaches to Stop Hypertension (DASH) study, high intake of fruits, vegetables, nuts and legumes, low-fat dairy, whole grains, low intake of sodium, sweetened beverages, and red and processed meats decrease the risk of incident kidney stones [7]. In postmenopausal women, greater intake of fiber, fruits, and vegetables was associated with a decreased risk of incident kidney stones [8]. Caffeinated coffee, decaffeinated coffee, tea, beer, and wine decreased the risk of incident stones, while apple juice and grapefruit juice increased the risk [9].

Being overweight or obese increases the risk for a kidney stone in both men and women [2]. Diabetes, gout, and lower household income also increased the risk of developing a kidney stone [2]. Stones are more common in warmer climates, where transdermal water losses are stimulated by ambient heat, leading to lower urine volume and more concentrated solute excretion [10].

Certain occupations may also increase the risk of kidney stones. For example, taxi cab drivers [11], who have infrequent access to rest rooms, are at higher risk, as are those who work in hot environments or with infrequent access to fluids, such as surgeons and nurses.

An initial evaluation of a kidney stone patient should include a detailed medical history. Bowel disease leading to chronic diarrhea and malabsorption increases the risk of kidney stones. Bariatric surgery (Roux-en-Y gastric bypass), small bowel resection, and ileostomy will increase risk. Systemic diseases that increase urine or serum calcium will also increase risk and include primary hyperparathyroidism and sarcoidosis. Carbonic anhydrase inhibitors, including topiramate, will increase risk by reducing urine citrate excretion.

### The gut microbiome

Nontraditional risk factors for stones include consideration of the patient's microbiome, the environment created by the microorganisms associated with the patient. For example, *Oxalobacter formigenes* degrades oxalate in the intestinal tract. Patients who are colonized with this organism have fewer stones and lower urinary oxalate levels [12]. Antibiotics are known to affect the prevalence of this organism in the human intestinal tract [13].

Antibiotic use is also associated with an increased risk of kidney stones [14]. Antibiotic use could affect stone risk by altering a patient's microbiome. Probiotics do not decrease urinary oxalate levels [15].

### Stone formation

The urine of most individuals consuming the "Western diet" is supersaturated at least sometimes with respect to calcium and oxalate, meaning that the potential for stone formation exists in most people. However, clinical stone disease occurs in only a small subset of the population. Much work has gone into understanding how stones form in the urine. At high concentrations of calcium and oxalate, homogeneous nucleation of crystals may occur spontaneously, but these levels are not commonly observed. However, at the calcium and oxalate concentrations more typically observed, spontaneous crystal formation is less likely, and, thus, stone formation may not occur even in the presence of urine supersaturated with respect to calcium and oxalate. The key step, therefore, in the formation of a stone is the formation of the initial crystal nidus. Many years ago, Randall hypothesized that areas of apatite plaque in the renal tubule serve as a base for stone formation and development, serving as an initial nidus where stones can attach and grow. Once a nidus has formed, the potential exists for stone growth in situations where the free concentrations of oxalate and calcium exceed the solubility of calcium oxalate. Thus conditions in which increased oxalate or calcium concentration in the urine occur increase the likelihood of stone formation. Other factors, however, affect stone formation as well.

Promoters of stone formation include low urine volume, sodium, low urine pH, and urate. In contrast, other urinary components, including inorganic compounds like citrate and magnesium, or organic compounds, such as osteopontin, urinary prothrombin fragment 1, and glycosaminoglycans, serve as inhibitors to stone formation. These organic compounds are thought to adsorb to the surface of the crystal, directly inhibiting further crystal growth. In addition, small amounts of other inorganic compounds such as zinc, composing the "elementome," may be important in stone formation [16].

Stones may also be caused by contaminants in food such as silica in milk, or melamine in infant formula.

### Goals for the treatment of recurrent stone formers

For patients who have already had a kidney stone, the goal of therapy is to transform the urine from one

that is lithogenic to one that is undersaturated in terms of likelihood of crystal formation. Saturation is defined as the ratio of the concentration of a substance in the urine to the solubility of the substance. For example, calcium oxalate saturation can be calculated from a 24-hour urine collection by measuring the urine calcium and oxalate concentrations, and the urine pH. Commercial laboratories report urine supersaturation for most stone types using a computer program called EQUIL2 [17]. The key factors in determining supersaturation for stone types include calcium and oxalate for calcium oxalate stones, calcium phosphate and pH for calcium phosphate (apatite or brushite) stones, and urate and pH for uric acid stones.

The goal for therapy is to keep the saturation below the level at which crystal growth will occur. This level is often lower in stone formers than nonstone formers because the kidney may already contain nucleation sites (Randall's plaques or existing stones or stone fragments).

The American Urologic Association (AUA) [18], the European Association of Urology (EAU) [19], and other organizations have recently published dietary guidelines (generally expert opinion) for the management of kidney stones [20–22]. The following sections on fluid, calcium, protein, sodium, vitamin C, vitamin D, sugar, potassium, and phytate intake are specifically for calcium stone formers unless noted. At the end of each section, we give our specific recommendations for the nutrient involved.

## Fluid intake for recurrent stone formers

Increasing fluid intake is an appropriate first step in management for everyone with kidney stones. It is clearly the most important therapeutic manipulation as it is highly effective, inexpensive, and safe. It is well tolerated, except for the obvious effect to increase urinary frequency, which may not be appreciated by people in certain occupations or with lower urinary tract obstruction, such as benign prostatic hypertrophy. Increasing urine volume with ingestion of water led to a reduced propensity for the crystallization of calcium oxalate [23]. Fluid intake of 2 L or more a day was shown in a randomized trial to decrease the 5-year rate of stone recurrence by more than half, from 27% to 12%. Baseline fluid intake was lower in stone formers compared to controls without stones [24]. Data from prospective cohort studies also show that higher fluid intake is associated with fewer incident stones [25]. A recent meta-analysis also found a significantly reduced risk of incident stones with high fluid consumption [26]. Both the AUA and EAU dietary guidelines address fluid intake. The AUA suggests sufficient fluid for a urine volume >2.5 L daily [18]. The EAU suggests fluid

intake of 2.5–3.0 L daily, with circadian drinking of neutral pH beverages, with a goal urine output of 2.0–2.5 L daily and a urine specific gravity <1.010 [19].

## *Affect of the type of fluid on stone risk*

Mineral water may contain calcium, magnesium, sodium, and bicarbonate. In one study, patients with kidney stones were asked to drink mineral water with varying amounts of calcium. Patients who had mineral water with the highest calcium had higher urinary calcium but lower urinary oxalate with similar calcium oxalate saturations [27]. Another study evaluated the changes in urine chemistries in subjects given a standard diet and either mineral water rich in magnesium, calcium, and bicarbonate or neutral fruit tea. Those who received the mineral water (drunk between meals) had higher urinary pH, magnesium and citrate excretion, and higher calcium excretion. The relative supersaturation of calcium oxalate did not change [28]. In the follow-up phase of the study, subjects told to drink 1.4 L of mineral water daily had improved calcium oxalate saturations primarily due to a higher urine volume. High-bicarbonate mineral water increased urinary pH and citrate [29]. However, it may also increase the activity product for calcium phosphate stones [30].

In general, water with magnesium, modest amounts of calcium (30 mmol/L or less), and alkali (bicarbonate) may be beneficial for patients with calcium oxalate or uric acid stones and has not been shown to be deleterious for stone formation.

## Caffeine, coffee, and tea

Caffeine intake causes both natriuresis and diuresis [31] and leads to an increased urinary calcium, magnesium, citrate, and sodium [32]. However, ingestion of caffeine-containing beverages is associated with a lower risk of incident kidney stones in the HPFS, and NHS I and NHS II cohorts [33]. The intake of caffeine was associated with higher urine volume, calcium, potassium, and lower urine oxalate and supersaturation for calcium oxalate and uric acid [33]. A decreased incidence of stones with increasing coffee intake was also seen in the Vietnam Era Twin registry, with those who drank five or more cups of coffee a day half as likely to develop kidney stones as those who did not drink coffee [34].

Black tea has more caffeine and more oxalate [35] than green or herbal tea. In observational studies, tea drinking is generally associated with a decreased risk of kidney stones [36–38], although one smaller study from northern China found the opposite association [39]. Massively excessive intake of tea has occasionally been reported to lead to oxalate nephropathy.

### Beverages containing citrate

Citrate has a dual role in the management of kidney stones. Citrate in the urine complexes with calcium, reducing relative saturation and the risk of stone formation. It also inhibits crystals clumping together, an effect called aggregation, and as the size of the crystals increases, citrate inhibits their agglomeration. Importantly these latter effects decreasing the risk of stone formation are not reflected in the supersaturation equations used to determine the risk of crystallization. Citrate is also used to alkalinize the urine. Dietary citrate is metabolized by the liver and kidney and consumes a proton, the equivalent of generating bicarbonate. The resulting alkalosis inhibits proximal tubule citrate reabsorption by the sodium dicarboxylate cotransporter, leading to more urinary citrate and a higher urine pH. Potassium citrate or potassium bicarbonate is, thus, often prescribed, particularly for the treatment of calcium oxalate, uric acid, cystine stones, or for calcium phosphate stones in distal renal tubular acidosis (RTA). Thus most recurrent stone formers benefit from high citrate intake. Achieving this can be difficult as medication is often prescribed two to three times daily (for a daily dose of 30–60 mEq) and compliance can be a major issue. Eating less animal protein yields less protons, which has the same effect to increase urine citrate as increasing ingestion of fruits and vegetables.

Most studies demonstrate some increase in urine pH and citrate content with ingestion of orange juice, lemon juice, lemonade, high-citrate sodas, and powdered beverages and have been extensively reviewed [40,41]. Table 36.1 shows a summary of alkali content (usually citrate and/or malate) content of various beverages.

Clearly, the volumes required of any of the beverages listed earlier would not be feasible to drink

daily on a routine basis. We, therefore, consider these beverages as adjuncts to therapy and not replacement for citrate or bicarbonate therapy. In general, we suggest sugar-free Crystal Light, or orange juice for patients with low urinary citrate or low urinary pH who want a sweetened beverage. Pineapple or melon juice (300 mL of blended fruit with 85 mL of water) may be attractive alternatives. Although non-colas (sodas) generally have a high citrate content, both sugar sweetened and artificially sweetened non-colas are associated with an increased risk of kidney stones based on population cohort studies [36] and, therefore, are not recommended. The additional calories of these beverages are also undesirable.

Lemon juice contains a high amount of citric acid which does not generate net bicarbonate when metabolized and, therefore, is not expected to have much benefit and is not recommended. However, citrus juices also contain other citrate salts which do yield net alkali. With a higher pH, orange juice contains more potassium citrate and less citric acid than lemon juice and, therefore, has greater utility for stone prevention [46]. Multiple studies have explored the role of lemonade in the management of hypocitraturic stone disease. Two studies that showed benefit did not specifically control for the type or amount of sweetener used [47,48]. In another study, lemonade showed no benefit to increase to increase urinary citrate or pH but did improve urinary output [49]. Another study compared lemonade therapy to lemonade and potassium citrate and found that the combination was more effective in increasing urinary citrate [50].

Consumption of sugar sweetened colas, non-colas, and punch are all associated with an increased incidence of kidney stones [36].

TABLE 36.1 Citrate equivalents of various beverages [42–45].

Beverage	Citrate (mmol/L)	Amount 30 mEq of alkali (L)	Amount 60 mEq of alkali (L)
Orange juice (citrate and malate)	36	0.83	1.6
Lemon juice	48	0.63	1.25
Lemonade <sup>a</sup>	17–39	1.07	2.1
Pineapple juice	42	0.71	1.4
Coconut water (citrate and malate)	14	2.14	4.28
Sodas with citrate <sup>b</sup>	8–11	3.16	6.3
Crystal Light	38	0.8	1.6
Melon (citrate and malate)	46.7	0.6	1.3

<sup>a</sup>Most of the citrate in lemon juice is in the form of citric acid, limiting the net alkali load.

<sup>b</sup>Sodas with high citrate are generally orange or citrus flavored: 7Up, Orange, Sierra Mist, Ginger Ale.

Adapted from Patel RM, Jiang P, Asplin J, Granja I, Capretz T, Osann K, et al. Coconut water: an unexpected source of urinary citrate. *BioMed Res Int* 2018;2018:3061742; Halebian GE, Leita VA, Pierre SA, Robinson MR, Albala DM, Ribeiro AA, et al. Assessment of citrate concentrations in citrus fruit-based juices and beverages: implications for management of hypocitraturic nephrolithiasis. *J Endourol* 2008;22(6):1359–66; Eisner BH, Asplin JR, Goldfarb DS, Ahmad A, Stoller ML. Citrate, malate and alkali content in commonly consumed diet sodas: implications for nephrolithiasis treatment. *J Urol* 2010;183(6):2419–23; Baia Lda C, Baxmann AC, Moreira SR, Holmes RP, Heilberg IP. Noncitrus alkaline fruit: a dietary alternative for the treatment of hypocitraturic stone formers. *J Endourol* 2012;26(9):1221–6.

Grapefruit juice intake was noted in population cohort studies to increase risk of incident kidney stones [9,51]; however, a short-term study showed no increase in lithogenicity with grapefruit juice ingestion [52]. A recent metaanalysis found that citrus-based products increase urinary citrate significantly [53].

## Calcium intake

Calcium absorption, calcium–protein binding in blood (only unbound calcium is filtered), and the renal handling of calcium affect the amount of calcium in the urine. Intestinal calcium absorption is regulated by 1,25-vitamin D. Calcium stone formers are known to have elevated 1,25-vitamin D levels [54], consistent with high urinary calcium levels being the most common metabolic abnormality in stone formers. Calcium reabsorption from the nephron is influenced by sodium. Volume depletion and low urinary sodium lead to increased calcium uptake by the kidney. Sodium excess will increase calcium excretion. Limiting calcium intake will decrease urinary calcium but will not decrease the risk of recurrent stones.

This effect was shown in a clinical trial by Borghi's group in which Italian men with recurrent calcium-containing stones, who had urine calcium excretion greater than 300 mg/d, were randomized to a diet that contained a "normal" amount of calcium (30 mmol or 1200 mg), low protein (52 g a day) and low salt (50 mmol of sodium) versus low calcium (10 mmol, or 400 mg), low protein, and low salt [55]. Both arms were advised regarding the restriction of oxalate intake. The "normal" calcium-containing diet is actually a relatively high calcium intake in most current urban populations. Compared with the low-calcium diet, the higher calcium diet was associated with

nearly half as many recurrent stones after 5 years (Fig. 36.1). Based on the findings of population-based studies showing lower incidence of stones with higher calcium intake [25] and review of existing clinical trials, both the AUA [18] and the EAU [19] recommend dietary calcium intake 1000–1200 mg daily, limited sodium, and limited animal protein for patients with calcium-containing stones. A recent Cochrane review also concluded that there was a benefit from a normal-calcium, low-protein, and low-salt diet for stone patients with higher urine calcium excretion [56].

The effect of increasing calcium intake is attributed to the binding of oxalate in the intestinal lumen, limiting its absorption. Data from the HPFS, NHS I and II show only a slight increase in urinary calcium with increasing calcium intake about 18 mg/d more in those from the highest quintile of calcium intake versus those from the lowest [57]. The inverse relationship between increased calcium intake and decreased urinary oxalate has also been demonstrated [58]; however, a retrospective analysis of Swiss kidney stone formers showed that a diet low in sodium and calcium did not increase urinary oxalate [59].

The Women's Health Initiative examined the role of calcium and vitamin D supplementation for the prevention of fractures in healthy postmenopausal women. Daily calcium (1000 mg of calcium carbonate) and vitamin D (400 IU of D3) resulted in a small but significant improvement in hip bone mineral density but did not reduce hip fracture. However, there was an increased incidence of kidney stones in the group receiving supplementation [60]. A subsequent analysis of these data showed a modest increase in the risk of cardiovascular events associated with the use of calcium supplements [61]; however, this topic remains controversial [62]. The USPSTF recommends against 25-OH vitamin D supplementation for the prevention of fractures; however, calcium and vitamin D supplements are still important in

FIGURE 36.1 Kaplan–Meier estimates of the cumulative incidence of recurrent stones, according to the assigned diet.

the treatment of bone disease [63,64]. Urinary calcium concentration and, therefore, the risk of kidney stone formation could be effectively mitigated in patients taking 500 mg/d in calcium supplements if the urine volume was greater than 2 L daily [65].

Therefore we recommend 800 IU of vitamin D3, and 1200 mg of calcium in the form of calcium-rich foods, not supplements, along with fluid intake of 2–3 L daily, for our stone patients who are postmenopausal or have been diagnosed with osteopenia or osteoporosis. In those lactose-intolerant patients, we recommend lactose-free dairy products and calcium-fortified orange juice. If calcium supplements are absolutely necessary, we prefer calcium citrate, which may have a slightly more favorable effect on urinary supersaturation [66]. In addition, calcium citrate should be taken with or shortly after meals in order to bind oxalate in the intestinal lumen and reduce its absorption. The effect of calcium supplementation on urinary calcium and supersaturations for calcium oxalate and calcium phosphate should also be monitored. Recent nontrial data demonstrate that bisphosphonates may reduce stone formation, so that medical therapy of reduced bone density may be preferred therapy for stone formers [67].

### Vitamin D intake

25-OH vitamin D deficiency is common in stone formers (roughly 30%) and is associated with higher parathyroid hormone levels [68]. However, 25-OH vitamin D status (levels between 20 and 100 ng/mL) or 25-OH vitamin D intake (either dietary or supplemental) was not associated with kidney stone incidence [69,70], and 25-OH vitamin D levels were not associated with an increased risk of incident kidney stones [54]. Since 25-OH vitamin D deficiency is common, we and others [71] recommend repletion of vitamin D in patients with deficiency and appropriate dietary intake of vitamin D. Short-term repletion studies show no increase in urinary calcium excretion or supersaturation for calcium oxalate or calcium phosphate in known stone formers [72] and longer term studies show no increase in stone prevalence [73].

### Vitamin C intake

Vitamin C (ascorbic acid) is metabolized to oxalate and, therefore, can lead to higher urinary oxalate levels. Two independent groups have shown that vitamin C intake is associated with an increased risk of kidney stones in men [74,75]. It is interesting to note that there was no increase in the risk of incident stones

with multivitamin intake [75]. Based on these results, we encourage our stone patients to get vitamin C through dietary sources (citrus fruit intake) but not through supplements. We are neutral on the use of a non-calcium containing multivitamin.

### Zinc intake

Decreased zinc intake is associated with an increased incidence of calcium-containing kidney stones in adolescents [76] and, therefore, appropriate dietary intake should be encouraged.

### Protein intake

Rats fed a high-protein diet have higher urinary calcium excretion, higher urinary volumes, and lower urinary citrate. There was significant bone resorption in the higher protein group suggesting that bone loss was contributing to increased urinary calcium excretion [77]. In normal men a high-protein diet (2 g/kg/d) led to increased urinary calcium, urinary uric acid, and decreased urinary citrate [78]. Interestingly a high-sodium diet also led to increased urinary calcium and decreased urinary citrate, and the changes became more pronounced when the high-sodium and high-protein diets were combined [78]. A similar study in healthy women also showed an association of increased urinary calcium and net acid excretion with higher protein intake [79]. Epidemiologic data from the HPFS study show a modest increase in the risk of incident kidney stones with increased nondairy protein intake, but this was not found in the NHS I or NHS II studies [80]. This negative result may be partly due to the lower protein intake in these studies with the highest quintiles having only 64–73 g of protein daily. This same study showed a decrease in the risk of incident kidney stones in younger women (NHS II) with increased intake of dairy protein. A recent study from China showed an increase in incident stones with higher animal protein and nondairy animal protein intake but not with plant protein intake [81].

A low-carbohydrate, high-protein diet, now a common weight-loss strategy, increases urinary acid load and urinary calcium and decreases urinary citrate [82]. If protein intake is kept the same, a vegetarian diet decreased the risk of uric acid stones but not calcium-containing stones [83,84].

Guidance regarding optimal protein intake for kidney stone patients is lacking as two randomized trials failed to show a benefit for a low-protein diet [85,86].

Despite those negative trials and based on the effects of animal protein on urine chemistry, our practice is to discourage high-protein, low-carbohydrate

diets, and to encourage normal protein intake (0.8–1 g/kg/d), favoring a DASH dietary approach that incorporates low-fat dairy intake.

### Sugar intake

Ingestion of 100 g of glucose or sucrose led to an increase in urinary calcium excretion in both normal subjects and calcium stone formers [87]. Urinary calcium and oxalate also increase after fructose infusion [88]. Women (NHS I and NHS II) and men (HPFS) with higher fructose intake had a higher risk of incident kidney stones but other nonfructose carbohydrates were not associated with increased risk [89]. No trials have been conducted to further elucidate the role of sugars in kidney stone disease, but in general high sugar intake is discouraged.

### Phytate intake

Phytate or myo-inositol hexaphosphate is found in beans, grains, nuts, and seeds. Phytate inhibits kidney stone formation by complexing with calcium and preventing crystallization. Younger women (NHS II) with higher phytate intake had a lower risk of kidney stones compared to those with lower phytate intake [90]. Urinary phytate levels are lower in stone formers compared to nonstone formers, and a diet free of phytate will decrease urinary phytate by 50% [91]. Western diets are typically low in phytate, while vegetarian diets are higher [92]. High dose of sodium phytate in patients with higher urine calcium excretion led to a decrease in urinary calcium excretion [93] but this treatment approach has not been recently studied.

### Sodium intake

Low sodium intake is generally prescribed for calcium kidney stone formers (Table 36.2). High salt intake leads to mild volume overload, inhibition of the renin–angiotensin system and decreased renal sodium uptake, and, therefore, decreased passive calcium uptake resulting in higher urinary calcium. Every 100 mEq of sodium increases urine output of calcium by about 24 mg [94], which may only be clinically significant when very high quantities of sodium are chronically ingested, as typical urinary calcium excretion is about 150–250 mg daily, and sodium intake is typically 80–200 mEq daily. However, the effect of sodium intake on urinary calcium seems higher from clinical trial data.

Stone formers have higher sodium ingestion and higher urinary calcium than nonstone formers [95]. Stone formers with higher urine calcium excretion

treated with mild calcium restriction (500–700 mg/d) had a decrease in urinary calcium on a low-sodium (80 mEq daily) compared to no-sodium restriction [96]. A larger, randomized controlled study showed that stone formers in idiopathic higher urine calcium excretion on a low-salt diet had significantly lower urinary calcium than those on the control diet (water therapy alone) [97] with a reduction of about 64 mg of calcium for every 100-mEq decrease in sodium. Successful restriction of sodium intake was considered an important reason for the success of the diet with higher calcium intake described earlier (PMID: <https://pubmed.ncbi.nlm.nih.gov/11784873/>).

However, the reduction of sodium intake will not be beneficial to stone formers with a tendency toward volume depletion (from chronic diarrhea or another bowel pathology). An elegant study showed that calcium stone formers with hypocitraturia benefited from sodium chloride intake with an increase in urine volume and a decrease in the supersaturation for calcium oxalate stones [98]. Since lowering urine calcium excretion is generally advisable, regardless of how high it may be, advising less salt intake is usually appropriate.

### Dietary management of idiopathic hyperoxaluria

Hyperoxaluria can also occur as a byproduct of excessive dietary intake, although this is usually not the primary cause of oxalate-containing stones [99]. Oxalate intake does not differ between stone and nonstone formers [99]. Although oxalate is found in a variety of foods of plant origin such as nuts, cocoa, and dark leafy greens, the most common sources of oxalate in an American diet tend to be spinach (cooked and raw), potatoes, and cold cereals. Low calcium intake is typically associated with greater oxaluria, as the absence of intestinal calcium favors oxalate absorption from the gut over oxalate precipitation and excretion from the gut. The risk of incident stones was higher in men with high oxalate and low calcium intake ( $P = .08$  for the interaction) [99].

In normal subjects the elimination of fruit and vegetables led to decreased excretion of urinary potassium, magnesium, citrate, and oxalate and increased the excretion of calcium and ammonium [100]. Although high oxalate diets can slightly increase the risk of an incident kidney stone [99] and low-oxalate diets reduce urinary oxalate [15], the concern is that asking patients to restrict some high oxalate foods may have unintended negative consequences. An elegant study by Noori et al. evaluated the 24-hour urine profiles of patients with calcium oxalate stones and hyperoxaluria who were placed on either a low-oxalate or

**TABLE 36.2** Comparison of American Urologic Association (AUA), European Association of Urology (EAU), and Canadian Urology Association (CUA) guidelines for dietary management of metabolic risks for kidney stones.

Dietary Component	AUA	EAU	CUA
Fluid	All stone formers should have fluid intake that will achieve a urine volume of 2.5 L daily	Fluid intake of 2.5–3.0 L/d Circadian drinking Neutral pH beverages Goal urine output of 2.0–2.5 L/daily Goal specific gravity (SG) <1.010	All stone formers should be counseled to achieve a daily urine output of 2.5 L
Calcium	Patients with calcium stones and high urinary calcium should limit sodium intake and consume 1000–1200 mg daily of dietary calcium	Normal calcium content (1–1.2 g/d)	The goal of dietary intake should be 1000–1200 mg/d  Should calcium supplementation in a patient with calcium oxalate stone disease be required, calcium supplementation should be taken at mealtimes
Vitamin D	None	None	In calcium oxalate stone formers with documented vitamin D deficiency, repletion is appropriate but monitoring for higher urine calcium excretion is suggested
Oxalate	Patients with calcium oxalate stones and high urinary oxalate should limit the intake of oxalate-rich foods and maintain normal calcium consumption	If a 24-h urine shows hyperoxaluria, oxalate should be restricted	Patients with calcium stones and hyperoxaluria should have moderate calcium and oxalate intake
Protein	Specific restrictions only if uric acid, low citrate in 24-h urine, or with cystine stones	Limited animal protein 0.8–1.0 g/kg/d	In patients with recurrent calcium oxalate or uric acid nephrolithiasis moderation of animal protein intake and avoidance of purine rich foods is suggested
Sodium	<100 mEq or 2300 mg daily	Limited sodium chloride (4–5 g/d)	Patients with recurrent calcium nephrolithiasis should aim for sodium intake of 1500 mg daily not to exceed 2300 mg daily
Fruits and vegetables		Balanced diet rich in fruits and vegetables	A diet high in fiber, fruits, and vegetables may offer a small protective effect against stone formation
Vitamin C	None	None	Vitamin C supplementation of >1000 mg daily is not recommended due to the associated risk of hyperoxaluria and nephrolithiasis
<b>Lifestyle advice</b>	<b>AUA</b>	<b>EAU</b>	<b>CUA</b>
	None	Lifestyle advice BMI for adults: 18–25 kg/m <sup>2</sup> Stress limitation measures Adequate physical activity Balancing excessive fluid loss	None
<b>Metabolic risk based on 24 h urine</b>	<b>AUA</b>	<b>EAU</b>	<b>CUA</b>
High uric acid	Patients with uric acid stones or calcium stones with high urinary uric acid should limit nondairy animal protein	No specific dietary guideline. Medications suggested	Limit animal protein and purine intake
Low citrate	Patients with calcium stones and low urinary citrate should increase the intake of fruits and vegetables and limit nondairy animal protein	No specific dietary guideline. Alkaline citrate suggested	Eliminate reversible causes Increase citrate-rich foods
High urea		Avoid excessive intake of animal protein	
Low magnesium		Magnesium supplementation 200–400 mg/d

DASH-style diet [101]. There was a trend toward higher oxalate excretion on the DASH-style diet; however, the calcium oxalate supersaturation also decreased in the DASH versus low-oxalate group, driven by an increase in urine pH, urinary magnesium, and citrate. Therefore in patients with idiopathic hyperoxaluria, we do not restrict intake of high-oxalate foods, unless we unearth an unusual excessive intake of a high-oxalate food such as rhubarb or peanut butter. Instead we encourage good dietary calcium intake with meals, and high intake of fruits and vegetables. Care is different for patients with secondary hyperoxaluria, as discussed next.

### Management of secondary hyperoxaluria

Intestinal disorders predispose to calcium nephrolithiasis in a variety of ways. Volume loss from frequent diarrhea results in decreased urine volume and, thus, a more concentrated urine [102]. Similarly, the systemic acidemia that results from stool bicarbonate losses leads to hypocitraturia and a lower urine pH, important risk factors for calcium stones [102]. Acidemia may also drive liberation of bone calcium, leading to an increase in urine calcium (and lower bone mineral density).

Enteric (secondary) hyperoxaluria, a complication of some intestinal disorders, is commonly observed in fat malabsorption disorders such as Crohn's disease, short bowel syndrome, in intestinal bypass procedures done for obesity [103], and with treatment with obesity drugs such as orlistat (which induces fat malabsorption). Calcium normally serves to bind oxalate in the gut and to prevent its absorption. It is believed that malabsorbed fat adsorbs calcium in the gut. The reduction in free calcium caused by fat malabsorption in these disorders leads to a significant increase in oxalate absorption. The colon is the major site of oxalate absorption, where bile salts also have an effect to increase oxalate absorption [104].

Avoidance of a high-fat, high-oxalate diet is recommended for the treatment of secondary hyperoxaluria. In addition, calcium supplements are recommended with meals, and cholestyramine has been recommended to bind excess fatty acids as well. Given that the hyperoxaluria in these disorders has been associated not just with nephrolithiasis, but also acute and chronic oxalate nephropathy and occasionally end-stage kidney disease (ESKD), therapy directed at hyperoxaluria must be aggressive in these circumstances. Oral enzyme therapy that degrades oxalate may be beneficial [105].

The AUA [18], EAU [19], and Canadian Urology Association [22] all published dietary guidelines for the management of kidney stones. These papers

represent a major advancement in the field as for the first time there is expert consensus on best practices. A summary of the major guidelines regarding dietary intake are shown in Table 36.2. All agree on appropriate fluid, calcium, sodium, and oxalate intake. Some of the associations discuss other specific aspects such as lifestyle (important given the association of diabetes and obesity with kidney stones), vitamin C, vitamin D, and magnesium intake.

### Uric acid stones

Low urine pH is the most common cause of uric acid stones [106]. Uric acid stone formers have a higher incidence of diabetes or glucose intolerance and less urinary ammonium resulting in hypocitraturia and low urine pH. Dietary management focuses on citrate replacement, appropriate fluid intake, and avoidance of excess protein intake. Given the highly positive effects of citrate supplementation, no randomized trials of diet for the prevention of uric acid stones have been performed. Protein restriction leads to two potential effects. Most importantly, it may lead to an increase in urine pH, reducing uric acid supersaturation. Second, it reduces uricosuria. However, reducing uricosuria is not likely to be useful if an "unduly acid urine pH" is not corrected.

### Cystine stones

Patients with this genetic disorder resulting in a defect in proximal tubular uptake of cystine, ornithine, lysine, and arginine are at risk of forming cystine stones. Cystine is relatively insoluble in urine, particularly at low pH. The goals of therapy for cystine stones include alkalinizing the urine to increase cystine solubility, reducing the concentration of cystine in the urine below the threshold for precipitation (generally about 243 mg/L or 1 mmol/L) by increasing fluid intake, and maintaining cysteine in a soluble, monomeric state. No clinical trials of dietary manipulation for the prevention of cystine stones have been performed. However, we advise two prescriptions in order to change urine chemistry: restriction of animal protein intake and of sodium intake. Animal protein is a source of protons so that reducing protein intake is expected to increase urine pH and reduce the dose of potassium citrate supplementation required to achieve a higher urine pH. Protein intake is also a source of methionine, a precursor of cystine, and of cystine itself. A low-sodium diet can reduce urinary cystine excretion [107]. As with other stones, higher urine output has been shown to reduce the recurrence of cystine stones [108].

## Special considerations for stone formers

Nephrolithiasis is associated with a twofold increase risk of chronic kidney disease (CKD) and ESKD independent of other known CKD risk factors [109]. Some of the explanations may be patient-specific. For example, patients with the metabolic syndrome, diabetes mellitus, or hypertension are predisposed to nephrolithiasis as well as CKD. Patients with anatomic urinary tract abnormalities that predispose to stone formation may also be predisposed to renal disease, and those with infection stones may develop renal scarring due to chronic infection.

Recently, a large cohort study demonstrated that patients with nephrolithiasis have an approximately 18% increased risk of coronary artery disease (CAD) compared to nonstone formers [110]. The effect was more pronounced in women [HR of 1.18 (1.08–1.28) in NHS I and HR of 1.48 (1.23–1.78) in NHS II]. There was no association found in a cohort of men (HPFS). Alexander et al. conducted a cohort study of over 3 million members of the Alberta, Canada universal health-care system between 1997 and 2009. They found that compared to nonstone formers, stone formers had a higher risk of acute myocardial infarction, angioplasty, and coronary artery bypass surgery and a higher risk of stroke. The risk was more pronounced for younger people and for women [111]. The mechanisms underlying these associations, including lifestyle, genetics, or diet, remain to be discovered. New insights into the physiology of stone formation may illuminate the similarity of disease progression of CKD or the vascular calcification and inflammation that gives rise to CAD. The implications may be that a diet intended to prevent kidney stones may mitigate diabetes, metabolic syndrome, and high blood pressure while addressing the risk for CAD and low bone mineral density. For that reason, we also promote the US Dietary Guidelines for Americans 2015–20 which promote health in general. Although those guidelines do not specifically address kidney stones and have not been tested for that purpose, we believe that adherence to those guidelines would likely reduce stones, promote bone health, and reduce metabolic syndrome and its accompanying comorbidities (<https://health.gov/dietaryguidelines/2015/guidelines/>).

## Introduction

Hypertension is one of the most common chronic diseases. It is currently estimated that approximately 70 million people in the 45- to 75-year age group in the United States have hypertension [1]. The prevalence of hypertension appears to be increasing. Globally, 1.13 billion people were estimated to have raised blood pressure (BP) ( $\geq 140/90$  mmHg) in 2015, with the increase largely occurring in low and middle-income countries due to population growth [2]. The degree of severity of high BP and hypertension has been updated and reclassified in the 2017 ACC/AHA Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults as indicated in Table 37.1 [3]. It is important to stress that normal BP is now considered  $<120$  mmHg systolic (SBP) and  $<80$  mmHg diastolic (DBP) (Table 37.1).

The widespread concern over the high prevalence of hypertension is due to compelling evidence that it is a major cause of morbidity and mortality [4–6] and the recognition that lifestyle plays a major role in the pathogenesis and current high prevalence of hypertension. Hence, to the extent that hypertension is caused or intensified by unhealthy lifestyles, including unhealthy diets, it should, in theory, be preventable or treatable by modifying people's behavior. Overweight and obesity, particularly visceral obesity, low birth weight, high sodium chloride intakes, and increased or reduced intake of a number of other nutrients have been associated with increased BP [7–11]. In the past several decades, overweight and obesity have increased to epidemic proportions in industrialized countries, and the prevalence of these conditions is increasing rapidly in the developing world [10,12]. Worldwide, approximately 1.4 billion adults were estimated to be overweight or obese in 2005,

and the number of such individuals appears to be increasing and is projected to be 1.9–3.3 billion people by 2030 [13]. Thus the effects on BP of obesity, energy intake and excessive or deficient intakes of other nutrients have become a subject of great importance. Table 37.2 lists nutritional factors that may affect BP. This chapter will review first the relationships between BP and obesity and energy intake and then relationships between BP and the intake of other nutrients.

## Obesity and energy intake

### Body mass and obesity

In adults a common way of describing normal or desirable body weight or increased body fat is the body mass index (BMI), which is defined as weight, in kilogram, divided by the square of the height, in meters. Normal or desirable BMI is generally considered to be  $18.5\text{--}24.9$  kg/m<sup>2</sup>. Overweight is defined as a BMI of  $25.0\text{--}29.9$  kg/m<sup>2</sup>, and obesity as a BMI of  $30$  kg/m<sup>2</sup> or greater. Morbid obesity has been defined as a BMI of  $35.0$  kg/m<sup>2</sup> or greater [12]. Obesity has also been classified as class I (BMI,  $30\text{--}34.9$  kg/m<sup>2</sup>), class II (BMI,  $35.0\text{--}39.9$  kg/m<sup>2</sup>), and class III (BMI,  $\geq 40.0$  kg/m<sup>2</sup>) [14]. Overweight and obesity are considered to occur at a lower BMI in Asian peoples, because the direct association of BMI with increased risk for adverse cardiovascular outcomes, including hypertension, occurs at lower weights-for-height than in Caucasians [15–17]. Other, rather similar, BMI criteria for obesity have also been described.

Scientific evidence strongly links obesity with elevated BP. Obesity, by itself, appears to directly increase BP, and obese individuals are more likely to have elevated BP than nonobese subjects [10,17–19]. Even

TABLE 37.1 Classification of blood pressure (BP) for adults.

BP classification	SBP (mmHg)		DBP (mmHg)
Normal	<120	and	<80
Elevated	120–129	and	<80
Hypertension			
Stage 1	130–139	or	80–89
Stage 2	≥ 140	or	≥ 90

This classification is based on the average of two or more properly measured, seated blood pressure readings performed on each of two or more office visits. DBP, Diastolic blood pressure; SBP, systolic blood pressure.

Reprinted from the 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA guideline for the prevention, detection, evaluation, and management of high blood pressure in adults. *J Am Coll Cardiol* 2018;71:e127–248.

among older adults, a higher BMI is associated with increased risk for hypertension. In a study of adult family medicine patients, the prevalence of prehypertension (SBP 120–139 mmHg; DBP 80–89 mmHg) increased significantly as the BMI rose from overweight to obese to morbidly obese [20]. A study conducted in Italy on 7907 general participants (the Longevity Check-up 7+ study) demonstrated that higher BMI was associated with increased risks of hypertension (as indicated by at least one SBP ≥ 140 mmHg, DBP ≥ 90 mmHg, or antihypertensive drug use) [19]. Adjusted odds ratios (ORs) for hypertension for people who were overweight or class I, class II, and class III obesity, as compared to those with normal weights, were 1.73, 3.38, 4.62, and 6.53, respectively [19]. A gain in BMI or in body fat is associated with an increased risk of developing hypertension [21]. In obese people a low dietary energy intake that induces weight loss reduces BP [22,23]. A randomized controlled trial that investigated the effects of bariatric surgery on BP among patients with a BMI of 30–39.9 who were receiving two or more antihypertensive drugs showed that those who received the bariatric surgery experienced a significant reduction in both BMI and in the number of antihypertensive drugs they were taking as compared to those who received medical therapy alone [24] (see also Chapter 40: Nutritional and Metabolic Management of Obesity and The Metabolic Syndrome in Patients with Chronic Kidney Disease, and Chapter 41: Bariatric Surgery and Kidney Disease). BP is correlated with both fat cell size and number [18]. Obese individuals may have larger adipocytes with altered metabolic activity that may produce bioactive molecules that predispose to hypertension (e.g., leptin, angiotensinogen, free fatty acids, and reactive oxygen species) as discussed in the following paragraphs [25–27]. Adipose tissue of obese individuals may undergo enhanced infiltration of macrophages which engender an inflammatory state, as indicated later [26].

TABLE 37.2 Nutritional factors that may affect blood pressure<sup>a</sup>.

Nutritional factor	Effect of nutritional status or increased nutrient intake on blood pressure
Obesity	Increase <sup>b</sup>
Energy intake	May increase
Fat intake	May increase
PUFA intake <sup>c</sup>	May decrease
MUFA intake <sup>d</sup>	May decrease
Fructose, glucose intake	Increase
Protein, certain amino acid intakes	May decrease
Sodium intake	Increase <sup>b</sup>
Potassium intake	Decrease
Magnesium intake	May decrease
Calcium intake	Little or no effect <sup>e</sup>
Dietary fiber	May decrease
Alcohol intake	Increase
Green coffee bean extract	Decrease
Regular coffee (+) or (–) caffeine	Decrease
Green, oolong, or black tea	Decrease
Dark chocolate	May decrease
Olives/olive oil (that contain MUFA and phenolic compounds)	Decrease
Low-fat liquid dairy products (milk, yogurt)	May decrease
DASH/Mediterranean/Nordic diets	Decrease

<sup>a</sup>Some of the nutrients listed have been shown to either lower blood pressure or reduce the risk of developing hypertension, but the evidence that they do both is not always clear.

<sup>b</sup>Obesity and high sodium intakes have the greatest blood pressure-increasing effects.

<sup>c</sup>PUFA; polyunsaturated fatty acids.

<sup>d</sup>MUFA; monounsaturated fatty acid.

<sup>e</sup>Blood pressure effects of calcium are unclear. It is possible that calcium supplements may reduce blood pressure only in people who have low calcium intakes.

DASH, Dietary approaches to stop hypertension.

Two other common methods of characterizing obesity are the waist circumference or the waist:hip ratio. These measurements reflect the amount of abdominal visceral fat mass that is more closely associated with the adverse effects of excess body fat. The waist circumference and waist:hip ratio are independent risk factors for the development of hypertension, diabetes mellitus, and cardiovascular and total mortality [28,29]. An abdominal (waist) circumference 102 cm or greater in men and 88 cm or greater in women is considered to indicate abdominal obesity [28]. The ratio of

the circumference of the waist to the hip correlates directly with both SBP and DBP (i.e., the male fat distribution is correlated with the BP level) [9,18]. A meta-analysis of longitudinal studies demonstrated that both obesity ( $\text{BMI} \geq 30 \text{ kg/m}^2$ ) and waist circumference  $\geq 102/88 \text{ cm}$  were similarly associated with the risk of developing hypertension [30]. Moreover, the combination of abdominal obesity and truncal obesity (i.e., a ratio of the subscapular to the triceps skinfold thicknesses of 2.24 or greater in men and 1.32 or greater in women) is associated with an increased risk of hypertension. The risk of hypertension associated with this altered fat distribution varies according to race and ethnicity [31], and even lower waist circumferences are associated with increased cardiovascular risk in certain Asian populations [32,33] (e.g.,  $>87$  and  $>83 \text{ cm}$  in Japanese men and women, respectively [33]). These racial/ethnic differences concerning the quantity and location of body fat and hypertension are consistent with the results of several studies indicating that there is a gene–obesity interaction in the pathogenesis of hypertension in some people [34,35].

### Mechanisms by which increased body fat causes high blood pressure

Overweight and obesity are associated with many physiological and metabolic changes that promote hypertension, as indicated in Table 37.3, and which have been recently reviewed [26,36–38]. One such alteration is the elevated activity of the renin–angiotensin–aldosterone system (RAAS) [18,39]. Obesity is associated with increased plasma angiotensinogen, renin, aldosterone, and angiotensin-converting enzyme (ACE) levels and urinary aldosterone [40,41]. Plasma renin activity (PRA), relative to the intake of sodium chloride, may be disproportionately high [18,23]. PRA and plasma aldosterone levels decrease when obese individuals lose weight, and this decrease is independent of changes in the sodium intake [18]. In experimental animal models, adipocytes release factors that stimulate the release of aldosterone and other compounds that may activate the mineralocorticoid receptor and promote sodium retention [42].

Obese people who do not have heart failure or chronic kidney disease (CKD) and nonobese people with higher BMIs may have lower levels of serum or plasma probrain natriuretic peptide as well as the saluretic compound, brain natriuretic peptide [38,43–46]. Subcutaneous adipose tissue in obese hypertensive individuals displays a reduced ratio of the mRNA level for the natriuretic peptide membrane receptor, guanylyl cyclase type-A, which is activated by natriuretic peptides, as compared to the mRNA level for the natriuretic peptide clearance receptor, which clears

TABLE 37.3 Mechanisms of hypertension in obesity [398].

1. Activation of the RAAS:
  - a. Increased serum angiotensinogen, renin, aldosterone, and ACE levels are found in obesity
  - b. PRA, relative to sodium chloride intake, is increased in obese subjects
  - c. Adipose tissue releases factors that stimulate the release of aldosterone and other mineral corticoid compounds
2. Obese individuals often have increased sodium intake
3. Activation of the SNS:
  - a. Glucose ingestion increases plasma norepinephrine
  - b. Obese subjects have higher supine plasma epinephrine, norepinephrine and PRA, and greater norepinephrine response to upright posture and handgrip exercise
  - c. Weight loss leads to more normal plasma catecholamine levels
4. Thyroid hormone. Overeating increases triiodothyronine production. T3 increases beta-adrenaline receptors
5. Insulin resistance (causes increased renal NaCl reabsorption, SNS overactivity, proliferation of vascular smooth muscle cells)
6. Obesity-associated chronic kidney disease (e.g., from focal segmental glomerulosclerosis, diabetic nephropathy)
7. Release from adipose tissue of leptin, resistin (antagonizes insulin), proinflammatory cytokines (CRP, TNF $\alpha$ , IL-6, NEFAs), and reactive oxygen species. Rat studies indicate that these compounds may activate the mineralocorticoid receptor
8. Endothelin-1 (causes vasoconstriction, may impair nitric oxide synthesis capacity)
9. NEFAs Excessive nutrient intake may increase portal venous delivery of unsaturated NEFAs that are associated with increased blood pressure
10. Increased leptin levels, which may promote SNS activity
11. Low adiponectin levels in obesity. Low adiponectin is associated HTN, low nitric oxide production, and endothelial dysfunction
12. Obstructive sleep apnea (may increase SNS activity, cause endothelial dysfunction and enhance RAAS activity, and may be associated with low adiponectin levels)

ACE, Angiotensin-converting enzyme; CRP, C-reactive protein; HTN, hypertension; IL-6, interleukin-6; NEFA, nonesterified fatty acids; PRA, plasma renin activity; RAAS, renin–angiotensin–aldosterone system; SNS, sympathetic nervous system; TNF $\alpha$ , tumor necrosis factor- $\alpha$ .  
Reprinted with permission from the Savica V, Bellinghieri G, Kopple JD. The effect of nutrition on blood pressure. *Annu Rev Nutr* 2010;30:365–401.

these peptides [38,43]. These data suggest that in obesity, there may be reduced synthesis of the natriuretic peptide membrane receptor and increased synthesis of the receptor that clears the natriuretic peptide from plasma. These findings may explain why the natriuretic and diuretic response to atrial natriuretic peptide may be reduced in obesity [47].

The sympathetic nervous system (SNS) activity may be increased in both the metabolic syndrome and obesity [18,23,48]. Insulin resistance with hyperinsulinemia and elevated plasma leptin, which is common in obesity, increase SNS activity [23,48–51]. Obese subjects have higher supine plasma epinephrine, norepinephrine and PRA, increased urinary norepinephrine, and a greater norepinephrine response to upright posture and isometric handgrip exercise [52]. Weight reduction in these individuals reduces these hormones

to more normal plasma levels [52]. Glucose ingestion increases plasma norepinephrine and may raise plasma thyroid hormone. Overeating may enhance triiodothyronine production from thyroxine, and greater triiodothyronine levels may increase beta-adrenaline receptors [48,53]. In this regard, in a cross-sectional study, intake of sugar-sweetened beverages was directly related to SBP and DBP [54,55]. There was a direct relationship between dietary fructose and glucose and SBP and DBP in people with higher dietary sodium intakes [54]. A metaanalysis of prospective cohort studies demonstrated that intake of sugar-sweetened beverages was associated with an increased risk of incident hypertension [risk ratio, 1.12; 95% confidence interval (CI), 1.06–1.17] [55]. The PREMIER Trial (see later) also indicated that reduced intake of sugar-sweetened beverages was associated with decreased BP [56].

Obesity predisposes to obstructive sleep apnea [48,57,58]. Persons with increased episodes of apnea or hypopnea during sleep are at increased risk for developing hypertension [59]. Obstructive sleep apnea is associated with insulin resistance, increased SNS activity, endothelial dysfunction, enhanced RAAS activity, increased plasma leptin, and low serum adiponectin [48,57,60,61]. The severity of sleep apnea is related to increased activity of the RAAS [62]. These relationships may explain why obstructive sleep apnea–associated hypertension can be resistant to pharmacological therapy. When obstructive sleep apnea is treated effectively, there is commonly a reduction in SNS activity and a decrease in both daytime and nocturnal BP and in the refractoriness of hypertension to treatment [63,64]. Continuous positive airway pressure treatment of obstructive sleep apnea for 6 months tended to decrease 24-hour urinary aldosterone excretion. A greater decrease of urinary aldosterone excretion was found in the patients with the lower baseline minimum oxygen saturation levels, lower BMI, and nondipping BP patterns [62].

Obesity may also predispose to hypertension by promoting renal sodium retention through insulin resistance. Insulin promotes the intracellular transport of glucose by stimulating insulin receptor substrate-1 (IRS-1). Obesity induces IRS-1 resistance to the actions of insulin, and this appears to be a cause of the hyperglycemia and elevated insulin levels that occur in obesity. On the other hand, insulin stimulation of sodium reabsorption in the proximal tubules appears to be mediated primarily by stimulating insulin receptor substrate-2 (IRS-2) [36,65]. In isolated renal proximal tubules obtained from knockout mice for IRS-1, insulin still induces sodium reabsorption, presumably by activating IRS-2 [65]. However, insulin stimulation of sodium reabsorption is significantly reduced in knockout mice

for IRS-2 [65]. Thus the high circulating levels of insulin in obesity, which is in part due to IRS-1 resistance to insulin, may overly stimulate IRS-2 activity and thereby enhance renal tubular sodium reabsorption, sodium retention, salt-sensitive hypertension, and edema. Weight loss reduces resistance to insulin [66].

Obesity increases the risk of CKD due primarily to diabetes mellitus, hypertension, and focal and segmental glomerulosclerosis. These former two conditions often lead to diabetic nephropathy and/or hypertensive nephrosclerosis [37]. As discussed in Chapters 39–41, obesity also promotes proteinuria and accelerates the progression of many types of renal disease. CKD, in turn, may predispose to sodium retention and hypertension.

Obesity may be associated with increased plasma leptin levels and resistance to leptin [48,49], abnormal plasma levels of coagulation factors, and increased reactive oxygen species, inflammation, and endothelial dysfunction which may also contribute to hypertension [25,48,67,68]. Weight loss in overweight and obese adults improves conduit and resistance artery endothelial function and reduces plasma leptin [69]. Patients deficient in leptin or the leptin receptor exhibited significantly lower SBP [70]. However, evidence, somewhat conflicting, suggests that SBP did not increase in leptin-treated patients with lipodystrophy [71]. Also, increased leptin levels may contribute to SNS activation, sodium retention, and vascular resistance [37,49,72,73]. Leptin appears to facilitate aldosterone production via the CYP11B2 enzyme expressed in adrenal cortical cells [74]. This mechanism may be more evident in women, and leptin and aldosterone may play important roles in maintaining sodium and water during pregnancy [74].

Adipose tissue releases leptin, resistin (which antagonizes the actions of insulin), such proinflammatory cytokines as tumor necrosis factor- $\alpha$ , nonesterified fatty acids (NEFA), and reactive oxygen species [36]. Studies in rats suggest that these latter compounds may activate the mineralocorticoid receptor [36]. Endothelin-1 released from adipose tissue causes vasoconstriction and may impair nitric oxide synthesis. Excessive nutrient intake may also increase portal venous delivery of NEFAs which may elevate BP (see earlier). Serum adiponectin levels are reduced in obesity, and low adiponectin is associated with low nitric oxide production, endothelial dysfunction, and hypertension [75].

It has been proposed that obesity also induces dysfunction of the microvasculature by the release from adipose tissue of inflammatory cytokines, free fatty acids, and other vasoactive compounds [76]. These processes lead to obesity-associated altered physiology and rarefaction of the microcirculation.

The consequences may be increased microvascular resistance and impaired delivery of insulin and glucose to target tissues (e.g., skeletal muscle). These disorders may result in insulin resistance, glucose intolerance, possibly salt sensitivity, and increased risk of type 2 diabetes mellitus, hypertension, and cardiovascular disease [76].

It is evident that many of the foregoing processes may work additively to promote hypertension and particularly salt-sensitive hypertension in overweight and obese people. For example, the combination of hyperreninemia, hyperaldosteronism, other compounds with mineralocorticoid-like actions, hyperinsulinemia, increased SNS activity, CKD, a propensity to retain sodium, and polyphagia with excessive sodium intake may cause sodium chloride-sensitive hypertension [37,65,77,78]. Insulin resistance also may predispose to both increased activity of the renin-angiotensin system [39] and inflammation [79]. Increased SNS activity in association with increased endothelin-1 and other factors elaborated with obesity may promote endothelial and vascular dysfunction [37]. The metabolic actions of adipocytes appear to contribute importantly to many of these processes.

Obese individuals are at increased risk for the metabolic syndrome. The Adult Treatment Panel III of the National Cholesterol Education Program defines the metabolic syndrome as the presence of at least three of the following constellation of characteristics [80,81]: an increased abdominal waist circumference ( $>40$  inches in men;  $>35$  inches in women), elevated BP (130/85 mmHg or greater), hypertriglyceridemia (150 mg/dL or greater), low-serum high-density lipoprotein cholesterol ( $<40$  mg/dL in men and  $<50$  mg/dL in women), and a fasting blood glucose of 110 mg/dL or greater. Other expert groups have defined the metabolic syndrome somewhat differently, but the essence of these other definitions of the metabolic syndrome is similar to what is described here [80].

People with the metabolic syndrome are likely to have hypertension (which is also part of the metabolic syndrome) and are prone to develop diabetes mellitus, particularly type 2. They are also at high risk for cardiovascular, cerebral-vascular, and peripheral vascular disease. Due to this association with vascular disease, some investigators have expanded the concept of the metabolic syndrome to include other cardiovascular risk factors, and particularly those risk factors associated with inflammation [82], CKD, as well as cardiovascular disease [7]. Emerging evidence indicates that the metabolic syndrome, which includes obesity as one of its characteristics, is also associated with the increased production of aldosterone and activation of the mineralocorticoid receptor, and that these changes may promote inflammation, oxidative stress, and insulin resistance [83]. The usefulness of the concept of the

metabolic syndrome has recently been challenged, because it is argued that the hazard ratios (HRs) for morbidity and mortality associated with the metabolic syndrome may be no greater than the sum of the HRs of the individual components of the syndrome [84]. Some observers have described a direct association between hypertension and BMI, increased waist circumference, obesity, weight gain, diabetes mellitus, and nephrolithiasis [85–89].

Both calcium oxalate and uric acid stones, as well as elevated serum urate and altered urate metabolism, are associated with an increased prevalence of obesity, diabetes mellitus, and hypertension [85–88]. Several causes for these interrelationships have been proposed [86,88,90], but the exact mechanisms are not clearly established (EST). People who are psychologically depressed are also at greater risk for hypertension [91]. This association may be due, in part, to the greater likelihood that depressed people will have a high BMI [92]. Patients with depression are more likely to have sympathetic hyperactivity. Plasma levels of norepinephrine and its metabolite, 3-methoxy-4-hydroxyphenylglycol, were found to be higher in patients with major depression than in control patients [93]. Moreover, electroconvulsive therapy decreases plasma norepinephrine levels in parallel with the resolution of depression [94].

High energy intakes, independent of obesity, also seem to engender hypertension in obese individuals. Dornfeld and coworkers studied the BP of obese patients during and after treatment with a protein-sparing modified fast [95]. During this treatment, BP fell quickly and profoundly, even before much weight was lost. When the low-energy-formula diets were discontinued and regular foods were reintroduced into their diet, many of these individuals began to ingest excessive quantities of energy and regained weight. Interestingly, for a given body weight, the patients' SBPs and DBPs were significantly greater when these same patients were ingesting excessive energy intakes and gaining weight as compared to when they were at the same body weight but eating a calorie-deficient diet and losing weight. The excessive energy intake could be the cause of the greater BPs for a given body weight during weight gain as compared to weight loss. However, possible contributions to this elevated BP from metabolic processes associated with new fat deposition or from the excessive intake of other nutrients, such as sodium and chloride, cannot be excluded.

Among obese, normotensive individuals, short-term weight gain, weight loss, or weight gain followed by weight loss, as compared to those whose weight was stable, were associated with an increased risk of developing hypertension within 2 years [96]. A metaanalysis demonstrated that such fluctuations in body weight might be associated with an increased risk of death.

The HR for death in the group with the greatest fluctuations in body weight group was 1.45 (95% CI 1.29–1.63) compared to the reference group, although heterogeneity and publication biases were found in these analyses [97]. The reduction in BP that occurs with weight reduction does not appear to be due exclusively to a reduction in energy intake and fat mass. Obese individuals often have increased dietary sodium intake [98], which may also promote hypertension (see later). As indicated earlier, hyperinsulinemia and possibly alterations in the physiology and anatomy of the microcirculation, which are often present in obesity, tend to increase renal tubular sodium reabsorption. However, Reisin et al. provided evidence that in obese, hypertensive individuals, ingestion of low-calorie diets and weight loss, independent of a reduction in dietary sodium intake, can lower BP [22]. These investigators placed obese patients on an energy-restricted, weight-reduction diet. Each day each individual was fed an amount of sodium equal to the sodium content in his previous 24-hour urinary output. Even though the total body sodium content fell little if at all in these patients, they experienced a substantial fall in mean BP as they lost weight [22].

The foregoing considerations indicate that there are multifactorial causes for hypertension in overweight and obese people. Reduced dietary energy intake and weight loss in obese people probably reduces hypertension by a number of mechanisms. It is important to keep in mind that very obese individuals may have a falsely elevated BP when it is measured with a normal-sized BP cuff. For accurate BP measurements, the cuff size should be adjusted to the arm circumference of the patient and increased for individuals with large-arm circumferences and reduced for people with small-arm circumferences.

### Excess fat in neonates and children and low birth weights

Overweight children are at increased risk for hypertension as they become older. Obese children develop substantially increased numbers of adipocytes in their bodies that persist into adulthood, and this factor is considered to contribute to the difficulty in attaining normal fat mass in obese adult patients who were obese in childhood. On the other hand, children with low birth weights are also at greater risk of developing hypertension. This latter phenomenon was observed in the Helsinki study [99]. The low birth weights are often due to maternal malnutrition or to impaired ability to deliver nutrients to the fetus; for example, due to disorders in the placenta or reduced blood flow through the umbilical artery [100]. Low birth weight

children often gain excessive weight by the end of the first 10 or 15 years of life, and presumably their increased body mass may contribute to their increased risk of developing hypertension [99]. It has also been postulated that low birth weight children often have a smaller number of nephrons in their kidneys, which may predispose them to sodium chloride retention and, hence, hypertension [99]. Other metabolic derangements in low or high birth weight babies may predispose to the metabolic syndrome, obesity, and hypertension [100–103]. The finding that prenatal or perinatal exposure to certain environmental stresses, such as undernutrition or overnutrition, can be associated with the development of disorders in adulthood is now recognized as a potentially important pathogenic factor. This field of study is sometimes referred to as *the developmental origins of health and disease* [104].

### Fetal undernutrition

The Dutch Famine, which led to undernutrition of mothers and newborn infants in the Netherlands near the end of World War II, is an example of the long-term effects of fetal undernutrition on the propensity for obesity and hypertension [105]. Fetuses whose mothers were subjected to prenatal famine while the fetuses were in the second and, to a lesser extent, the third trimester of pregnancy in the Netherlands between November 1944 and May 1945, tended to be born with low birth weights. They were shown to be more likely to become overweight in childhood and to have a high prevalence of obesity, hypertension, and diabetes mellitus, among other disorders, when they aged into their 50s and 60s [105].

### Individual nutrients, miscellaneous substances, and blood pressure

#### Sodium chloride

There is abundant evidence for a direct relation between sodium chloride intake and BP [68,106–108]. Sodium chloride intake correlates directly with BP across population groups. The association of sodium chloride intake and BP increases with age, the BP level and the presence of renal insufficiency, and among individuals with a family history of hypertension. The International Study of Salt and Blood Pressure (INTERSALT) involved about 10,000 adults, aged 20–59 years old, who were evaluated at 52 centers in 32 countries. This study indicated that 24-hour urine sodium excretion was significantly and positively associated with the median SBP and DBP, the upward slope of SBP and DBP that occurs with age, and the

prevalence of elevated BP [108,109]. Other cross-sectional population-based studies describe a direct relationship between 24-hour urinary sodium and SBP, even after multivariate adjustments [110]. Even in normal adults, salt intake affects extracellular volume which, in turn, can affect the risk of hypertension; a reduction of dietary salt intake from 160 to 80 mEq/day reduces their body weight and extracellular volume by 1–1.5 L [111]. The chloride salt of sodium appears to have a substantially greater effect on raising BP than does sodium bicarbonate [112].

Among individuals of similar age and BP level, the pressure response to high sodium intakes varies greatly. The BP of some individuals rises with high sodium chloride intakes, whereas in other individuals, the BP does not appear to be affected by the sodium chloride intake [113]. Sodium chloride sensitivity can be diagnosed by a reduction in BP associated with low sodium chloride intake and/or an increase in BP with sodium chloride loading. Sodium chloride resistance has been defined as no rise or fall in BP after an increase or decrease in sodium chloride intake. It has been estimated that approximately 30%–50% of hypertensive persons and a smaller percentage of nonhypertensive persons are sodium chloride-sensitive. A limitation of these studies is that the testing for sodium chloride sensitivity with salt loading is generally carried out for only a few weeks or less. It is possible that a person whose BP does not increase during several weeks of sodium chloride loading, and is, therefore, classified as sodium chloride resistant, might be predisposed to hypertension if he chronically ingests large quantities of sodium chloride for many months or years. As indicated earlier, epidemiological observations support this consideration. Moreover, people who are not determined to be sodium chloride-sensitive in these short-term studies can subsequently develop diseases that render them sodium chloride-sensitive; for example, CKD or obesity. These matters are of substantial concern because the dietary sodium intakes in many societies are quite high and also because there is a high prevalence of hypertension among adults worldwide, particularly as people age. Reduction in sodium intake may be particularly effective in lowering BP in individuals who are older, obese, African-American, possibly in those who are female, and in those who have CKD, higher SBPs, or a greater SBP response to the cold pressor test [107,114].

Several metaanalyses have examined the effects of dietary salt reduction on BP [107,115–120]. A metaanalysis of randomized controlled trials that compared low sodium chloride intake (3–6 g/day) and high sodium chloride intake (10–12 g/day) in CKD stage 1–4 patients demonstrated that SBP, DBP, and both clinic and ambulatory BPs were lower with the low sodium intakes.

Moreover, urine total protein and albumin excretion were significantly lower with the low salt intakes [121]. A metaregression analysis, which investigated the magnitude of BP reduction in relation to lowering the sodium intake within the framework of a metaanalysis, was conducted in 133 randomized controlled trials. This study, which compared the effects of reduced sodium intake with usual sodium intake, demonstrated a strong, linear dose–response relationship between sodium reduction and BP reduction. This was especially evident in the individuals with a mean BP above the 75th percentile (131/78 mmHg or greater). The dose–response relationship was  $-7.7$  (95% CI,  $-10.4$ ,  $-5.0$ ) mmHg/100 mmol reduction in sodium intake for SBP and  $-3.0$  (95% CI,  $-4.6$ ,  $-1.4$ ) mmHg/100 mmol decrease in sodium intake for DBP [122]. It is noteworthy that some metaanalyses do not report a fall in BP with a reduction in sodium chloride intake in normotensive persons [117,120]. This discrepancy may be due to the inclusion in these latter studies of acute salt loading or salt restriction that was conducted for only short periods of time, sometimes for only 5 days. Large and abrupt reductions in salt intake can increase sympathetic tone, PRA and angiotensin II levels [118,120]. When only studies of 4 or more weeks' duration were included in the metaanalysis, modest restriction of salt intake (i.e., a reduction to 78 mmol or 4.6 g/day of NaCl) was associated with lowering of BP [120].

Simply following a “no added salt diet” may reduce SBP and DBP by an average of 12.1 and 6.8 mmHg during the day and 11.1 and 5.9 mmHg at night [123]. This “no added salt diet” is defined as no added sodium chloride to foods and no intake of salty foods; sodium chloride intake should be below 5.0 g/day with a urinary sodium excretion below 100 mEq/24 hours. An extensive Cochrane review of randomized studies of high-sodium versus low-sodium diets indicated that high-sodium diets slightly but significantly decreased SBP by  $-1.09$  (95% CI,  $-1.63$ ,  $-0.56$ ) mmHg in normotensive and by  $-5.51$  (95% CI,  $-6.45$ ,  $-4.57$ ) mmHg in hypertensive white people [124]. This latter metaanalysis also described highly significant increases in plasma renin, aldosterone, noradrenaline, adrenaline, cholesterol, and triglycerides with sodium restriction [124].

Obesity appears to increase the sensitivity of BP to sodium chloride intake in adolescents, possibly because of the hyperinsulinemia, hyperaldosteronism, and enhanced SNS activity that are commonly found in obese individuals [77]. Weight loss in these individuals appears to decrease their salt sensitivity. Patients with essential hypertension have higher urinary free cortisol excretion [125]. Hypertensive individuals who had higher urinary free cortisol excretion were found to have a lower reduction in SBP and mean arterial pressure in response to reduced sodium intake [125]. Moreover, baseline plasma renin concentrations, obtained at the onset of an 8-week

study, were inversely related to the magnitude of salt sensitivity, whereas the baseline plasma N-terminal atrial natriuretic peptide levels correlated directly with this phenomenon [126].

There is direct evidence for a genetic link for the association between hypertension and sodium intake and possibly obesity. In people 60 years of age or older, there was a linear increase in SBP and DBP with sodium loading [127]. This increase in BP with sodium loading was greatest in individuals with isolated systolic hypertension. The change in DBP in response to sodium loading varied in accordance with the type of gene polymorphism of the angiotensinogen gene, but not with regard to polymorphisms of the ACE gene [127]. Obese hypertensives who were homozygous (TT genotype) or heterozygous (TC + CC genotype) for the T-786 endothelial nitric oxide synthase (eNOS) gene were also studied [128]. The metabolic product of this enzyme, endothelial-derived nitric oxide (NOx), is a vasodilator. The heterozygous obese hypertensive patients with the TC + CC genotype, as compared to the homozygous TT genotype patients, had a greater increase in diastolic and mean arterial BP, and a significant decrease in renal plasma flow and glomerular filtration rate in response to sodium loading [128]. Moreover, with sodium loading, the TT genotype has a significantly greater increase in plasma NOx, whereas the TC + CC genotype had a borderline significant increase ( $P = .051$ ) in urinary NOx excretion.

Genetic polymorphism in the Klotho gene KL involving the single nucleotide rs9536314 is also associated with salt-sensitive hypertension in hypertensive humans [129]. Hypertensive patients with this polymorphism who receive an infusion of 0.9% saline have a greater rise in SBP, DBP, and mean BP as compared to those who do not have this polymorphism. The patients with this Klotho polymorphism also demonstrated a flatter BP–natriuresis relationship. Thus with an infusion of 0.9% saline, the ratio of the increase in natriuresis to the rise in mean BP was less than in people without this genetic polymorphism. There was also an inverse relationship between serum  $\alpha$ Klotho concentrations and the change in the mean BP after the saline infusion. These findings suggest that hypertensive patients with this gene polymorphism for Klotho not only are more likely to have salt-sensitive hypertension, but they also seem to require a higher BP to maintain the same magnitude of natriuresis-induced BP increase as do people without this gene difference.

BP in individuals with stage 4 [glomerular filtration rate (GFR) 15–29 mL/min/1.73 m<sup>2</sup>] or stage 5 (GFR < 15 mL/min/1.73 m<sup>2</sup>) CKD may be particularly sensitive to sodium loading or volume expansion [130,131]. Shaldon reported that in a 23-year-old male with chronic renal failure who was fed a

salt-restricted diet for 8 weeks, BP fell from 230/145 to 135/90 mmHg, and there was a reduction in headache, nausea, vomiting, and papilledema and an improvement in vision [132]. The reduction in BP may continue for months after the removal of body NaCl by dietary salt restriction and dialysis ultrafiltration. The authors speculate that this delayed response may be due to the decrease in nonosmotically active sodium which is possibly bound in proteoglycans and glycosaminoglycans in the interstitial matrix that lines the intimal surfaces of blood vessels [133].

A growing body of evidence suggests that high-sodium intakes may promote more rapid progression of chronic kidney failure, possibly by an increase in oxidative stress, albuminuria, and BP, and alterations in glomerular hemodynamics [133,134]. Some authorities have postulated that salt-sensitive hypertension may be caused by subtle injuries to the kidney. Such injuries may be associated with both renal microstructural and physiological abnormalities [135]. These disorders may cause an impaired ability to excrete a sodium load and the consequent development of volume expansion with attendant hypertension.

Patients whose nocturnal BP does not fall or decreases only slightly are designated as nondippers. Such patients are more likely to experience more severe terminal organ damage compared to nocturnal BP dippers. The kidneys can play an important role in determining the circadian rhythm of BP. Both sodium-restricted diets and diuretics may shift circadian BP patterns from nondipper to dipper status [136,137]. Patients with the metabolic syndrome also may be salt-sensitive in this regard; their nocturnal BP, which may not have decreased before the salt restriction, may fall after they ingest a sodium-restricted diet. The prevalence of salt-sensitive hypertension is higher in patients with the metabolic syndrome as compared to those without (70.6% vs 36.0%,  $P = .017$ ) [138]. Patients with primary aldosteronism also tend to exhibit a nondipper pattern of nocturnal BP. Their nocturnal BP fell after they reduced their sodium chloride intake from 10–12 to 2–4 g/day [139].

## Potassium

Epidemiological and clinical studies concerning potassium intake indicate that potassium supplements (e.g., 60–120 mEq/day) lower BP. But some randomized, prospective trials have yielded conflicting results. However, in a metaanalysis of 19 clinical trials involving 586 hypertensives, Cappuccio and MacGregor reported that oral potassium supplements significantly lowered both SBP and DBP by  $-5.9$  mmHg (95% CI,  $-6.6$  to  $-5.2$ )

and by  $-3.4$  mmHg ( $-4.0$  to  $-2.8$ ), respectively, in subjects with essential hypertension [140].

In the metaanalysis by Whelton and coworkers, potassium supplements were associated with a significant reduction in mean SBP and DBP of  $-3.11$  mmHg ( $-1.91$  to  $-4.31$  mmHg) and  $-1.97$  mmHg ( $-0.52$  to  $-3.42$  mmHg), respectively [141]. A more recent meta-analysis by Binia et al. found that an increase in the ratio of urinary potassium to sodium excretion as well as an absolute increase in urinary potassium per se was associated with a decrease in SBP: a  $-2.14$ -mmHg decrease in SBP (95% CI,  $0.15$ – $4.14$ ,  $P = .035$ ) was observed for each one-unit increase in the urinary Na/K ratio [142].

Potassium intake may lower BP by increasing renal sodium losses. Potassium deficiency, even of a mild nature, may induce renal sodium retention, increase BP and engender salt sensitivity [143–145]. Mu and associates presented evidence that supplements of potassium and calcium may prevent hypertension in adolescents by promoting urinary sodium excretion [146]. Pere and coworkers fed a high-sodium diet and administered cyclosporine A to 8-week-old spontaneously hypertensive rats [147]. The animals developed hypertension and renal injury associated with renal dopaminergic deficiency [147]. A combined dietary supplement of magnesium and potassium prevented hypertension in these rats.

An increased intake of potassium with a subsequent rise in serum potassium concentrations is associated with dephosphorylation and inactivation of the  $\text{Na}^+ - \text{Cl}^-$  cotransporter in the distal convoluted tubules of the kidney [148]. The epithelial  $\text{Na}^+$  channel—expressed downstream cannot fully reabsorb the increased sodium in the tubular fluid, and hence net sodium excretion into the urine increases. Potassium-deficient diets are particularly common in African-Americans and have been associated with the high prevalence of hypertension and sodium chloride sensitivity in these individuals.

There are a number of mechanisms by which potassium intake may lower elevated BP [149]. As indicated earlier, potassium intake may increase renal sodium excretion. Potassium may also modulate baroreflex sensitivity and directly cause vasodilation, or reduce cardiovascular reactivity to norepinephrine or angiotensin II. Potassium supplementation to Dahl rats augmented nitric oxide production and vascular dilatation [150]. Another study that investigated the effect of potassium supplementation on young Dahl rats (4 weeks of age) demonstrated that potassium supplementation inhibited sympathetic vasoconstriction rather than facilitated vasodilatory mechanisms [151]. Supplemental potassium,  $217$  mg/day, and magnesium,  $71$  mg/day, for 4 weeks increased small artery compliance and reduced BP in

patients with essential hypertension [152]. Thus it has been recommended that a substantial potassium intake should be maintained to prevent or treat hypertension, particularly in subjects who are unable to reduce their sodium intake and in those who are salt-sensitive or who have a family history of hypertension [149].

Nowson and coworkers reported that a reduction in sodium intake to about  $70$  mmol/day and an increase in dietary potassium to  $85$  mmol/day could maintain a lower BP and reduce the burden of cardiovascular disease [153]. Another study investigated the effects of a low-sodium high-potassium (LNAHK) diet on the BP response to antihypertensive medications. The LNAHK diet more effectively potentiated the actions of renin–angiotensin system inhibitors than other antihypertensive medications [154]. The Dietary Reference Intakes propose that adequate potassium intake is  $4.7$  g ( $120$  mmol)/day, which should lower BP and reduce the BP raising effects of sodium chloride [155]. In this regard, an increase in dietary potassium intake to  $120$  mmol/day abolished or suppressed the frequency or severity of salt sensitivity in normotensive African-American men to the levels found in normotensive white men [145]. Also, in a randomized, double-blind, prospective controlled trial of potassium supplementation,  $80$  mmol/day, or placebo for 21 days in normotensive or mildly hypertensive African-Americans ingesting a low,  $32$ – $35$  mmol/day, potassium diet, the potassium supplement significantly reduced their SBP and DBP [156]. A somewhat longer term, 6-week, randomized, double-blind, placebo-controlled trial in mostly normotensive adults of European descent that provided only  $24$  mmol/day of supplemental KCl showed that this modest potassium dose also significantly lowered mean arterial BP, SBP, and DBP [157]. However, in persons with normal BP, the BP-lowering effectiveness of potassium supplements appears to be limited [158].

It is relevant that a recent systematic review suggests that in early CKD (stages 1–2), but not in late CKD (stages 3–5), high potassium intakes protect against or slow progression of CKD and low potassium intakes may facilitate progression [159]. Notwithstanding the BP-lowering effects of dietary potassium and the possible slowing effects of dietary potassium on CKD progression, patients with advanced CKD are advised against ingesting large amounts of potassium, because hyperkalemia can be fatal. The use of medicines that block or inhibit the renin–angiotensin–aldosterone system predispose CKD patients to hyperkalemia. These medicines, especially when given to patients with diabetic nephropathy, who may have hyporeninemia or may be resistant to renin, can render these patients exquisitely sensitive to becoming hyperkalemic with potassium supplementation.

## Calcium

There is considerable controversy as to whether high calcium intakes lower BP. McCarron and coworkers conducted a series of studies suggesting that calcium supplementation lowers BP [160]. Indeed, they and others found an inverse correlation across populations and ethnic groups between the mean dietary calcium intake and BP levels [160–162]. The Nurses' Health Study initially found an inverse relationship between dietary calcium and BP after the first 4 years of follow-up [163]. With longer follow-up, no independent relationship between dietary calcium intake and BP could be demonstrated [164]. Cappuccio and coworkers carried out a metaanalysis of 23 observational studies and reported an inverse relationship between calcium intake (determined from dietary diaries and food-frequency questionnaires) and BP [165]. However, the effect was rather small, and there was evidence of publication bias and heterogeneity of data across the investigations.

Bucher and associates performed a metaanalysis of 33 randomized clinical trials of dietary calcium supplementation involving 2412 individuals with or without hypertension [166]. They described for the entire group a small but significant reduction in SBP of  $-1.27$  mmHg (95% CI,  $-2.25$  to  $-0.29$  mmHg;  $P = .01$ ) but no change in DBP ( $0.24$  mmHg; 95% CI,  $-0.92$ – $0.44$  mmHg;  $P = .49$ ). In six of these studies in which participants were classified according to whether they were hypertensive or not, there was a significant fall in SBP and DBP in the hypertensive individuals but not in the normotensives [166]. Allender and coworkers carried out a metaanalysis of 22 randomized clinical trials in 1231 individuals [167]. In this metaanalysis, calcium supplementation was associated with a statistically significant but not very clinically important reduction in SBP,  $-0.89$  mmHg (95% CI,  $-3.18$  to  $-0.18$  mmHg) and no significant change in DBP,  $-0.18$  mmHg (95% CI,  $-0.75$  to  $0.40$  mmHg). Griffith et al., in a large metaanalysis on the effects of supplemental calcium on BP, reported a reduction in SBP of  $-1.44$  mmHg (95% CI,  $-2.20$  to  $-0.68$ ,  $P < .001$ ) and in DBP of  $-0.84$  mmHg (95% CI,  $-1.44$  to  $-0.24$ ,  $P < .001$ ) [168]. Subjects in these studies were given calcium supplements of 400–2000 mg/day [164–168]. Calcium supplements that resulted in a median total daily calcium intake of about 1 g/day did not affect SBP or DBP in normotensive individuals [167–169]. Another metaanalysis reported that the BP-lowering effect of calcium intake was evident only in studies where dietary calcium intake was 1000 mg/day or greater [170]. In three small studies the supplemental calcium intake diminished the rise in BP response to a high sodium intake [169,171,172].

Calcium supplements may be effective in pregnant women. A metaanalysis on the effects of calcium supplementation during pregnancy demonstrated that calcium supplements reduced the risks of high BP, preeclampsia, preterm birth, and the composite outcome of maternal death or serious morbidity. These effects of calcium supplements were especially evident in women who had been eating low-calcium diets [173]. In addition, a qualitative metaanalysis indicated that maternal calcium intake tended to be directly associated with lower BPs in the offspring, especially during the first 2 years of their lives [174].

It has been suggested that discrepancies in the published results concerning the effects of calcium intake on BP may be related to the possibility that a low-calcium diet predisposes to hypertension, whereas in individuals who are already eating adequate calcium, higher intakes of calcium have little or no BP-lowering effect [166–168]. In this regard, Pan and coworkers gave calcium supplements to individuals with mild or moderate hypertension who lived in areas of China where there is both a higher prevalence of hypertension and a high salt and low calcium content of their diet. They reported that after 35 days of treatment with calcium lactate supplements that provided 800 mg of calcium/day, there was a reduction in SBP and DBP of  $-4.7$  ( $P = .027$ ) and  $-2.2$  ( $P = .074$ ) mmHg, respectively [175]. Further studies will be needed to resolve the question of whether a BP-lowering effect of calcium is largely or entirely limited to people ingesting calcium-deficient diets. In this regard the higher calcium intake in the dietary approaches to stop hypertension (DASH) combination diet and in low-fat dairy products might contribute to the BP-lowering effects of these regimens (see DASH diet later).

## Fish oil

There are two metaanalyses of controlled clinical trials examining the use of omega-3 fatty acids [176,177]. In the metaanalysis of Appel and coworkers concerning 11 trials that enrolled 728 normotensive individuals [176], omega-3 polyunsaturated fatty acids (PUFA) supplements led to a significant reduction in SBP and in DBP in only 2 and 1 of these trials, respectively. In six studies involving 291 untreated mildly hypertensive individuals, reductions in SBP and DBP were observed in two and four of the trials, respectively [176]. The weighted, pooled reductions in SBP and DBP in the normotensive individuals averaged  $-1.0$  (95% CI,  $-2.0$ – $0.0$ ) and  $-0.5$  (95% CI,  $-1.2$  to  $+0.2$ ) mmHg. In the trials of untreated hypertensive persons, the weighted, pooled decreases in SBP and DBP averaged  $-5.5$  ( $-8.1$  to  $-2.9$ ) and  $-3.5$  ( $-5.0$  to  $-2.1$ ) mmHg, respectively. The doses of omega-3

PUFA used in these studies tended to be rather high, usually 3 g/day or greater [176].

Morris et al. evaluated 31 placebo-controlled clinical trials involving 1356 subjects and showed, with fish oil use, a mean reduction in SBP of  $-3.0$  mmHg (95% CI,  $-4.5$ ,  $-1.5$  mmHg) and in DBP of  $-1.5$  mmHg (95% CI,  $-2.2$ ,  $-0.8$  mmHg) with a statistically significant dose–response relationship [177]. There was a dose–response relationship between fish oil dose and SBP and DBP reduction. The decrease in SBP and DBP was statistically significant in the hypertensive patients but not in the normotensive subjects, although the average fish oil dose used was slightly higher in the hypertensives (5.6 g/day) as compared to the normotensives (4.2 g/day) [177]. These metaanalyses indicate that in people who are assigned to a relatively high omega-3 fatty acid intake, there is a statistically significant reduction in BP in hypertensive individuals, and little or no effect in normotensive persons. However, a metaanalysis that examined the effects of supplemental PUFA on cardiovascular risk factors failed to demonstrate a significant reduction in either SBP or DBP in the individuals who ingested higher amounts of PUFA [178]. In a metaanalysis of cohort studies, only circulating levels of long-chain  $n-3$  PUFA, in contrast to the dietary intake of fatty acids or of fish, was associated with a lower incidence of elevated BP [179].

A randomized, prospective, double-blind clinical trial, in a  $2 \times 2$  design, compared the effects on BP of daily doses of  $n-3$  polyunsaturated fatty acids ( $n-3$  PUFA), 1200 mg, a combination of three B vitamins (5-methyl-tetrahydrofolate 560  $\mu$ g, vitamin B<sub>6</sub> 3 mg, and vitamin B<sub>12</sub> 20  $\mu$ g), both of these treatments combined, or placebo [180]. The  $n-3$  PUFA provided eicosapentaenoic acid and docosahexaenoic acid in a 2:1 ratio. The B vitamins were given, in part, to assess the effect of lowering plasma homocysteine on BP. A total of 2501 men and women with a history of cardiovascular disease were studied for 5 years. At baseline, their mean SBP and DBP (mmHg) averaged in the low 130 and 80 s, respectively, and they received a mean of 1.7 antihypertensive medications per subject. There was no effect of the  $n-3$  PUFA, the three B vitamins, or the combination of both of these supplements on SBP, DBP, or mean BP in these individuals. It is possible that a higher  $n-3$  PUFA dose than was used in this trial might have been more effective.

The mechanism by which fish oil may lower BP in hypertensive patients is not clear. It may be related to enhanced elaboration of prostaglandins which, in turn, may increase sodium and water excretion, promote vasodilation, and/or inhibit the release of thromboxane (a vasoconstrictor). Also, it is possible that prostaglandins may regulate renin release or decrease

responsiveness to vasopressor hormones.  $n-3$  PUFA might inhibit the beta-adrenergic system or activate eNOS [179,181–183]. The preponderance of studies with fish oil was of short duration ( $<3$  months). Longer term studies will be necessary to determine whether fish oil has a sustained antihypertensive effect in hypertensive persons and also to assess the optimal fish oil dose for BP lowering. There are a number of side effects with fish oil intake, including most commonly eructation and a bad or fishy taste [176,177]. It is worth considering that the higher percentage of polyunsaturated fatty acids in the DASH combination diet may also contribute to the reduced BP with this diet (see later).

## Olives, olive oil

Olives and olive oil are key ingredients of the Mediterranean diet and are thought to contribute to the BP-lowering effect of the diet. Olive oil contains substantial amounts of monounsaturated fatty acids (MUFAs) and phenolic compounds, both of which have been associated with a reduction in BP [184]. The effect of MUFA on BP has been investigated in observational and interventional studies. A prospective observational study (the European Prospective Investigation into Cancer and Nutrition study) conducted in Greece, and nine other European countries investigated the association between dietary, biological, lifestyle, and environmental factors and the etiology of cancer and other chronic diseases [185,186]. The results indicated that the amount of olive oil intake and the ratio of MUFA to saturated fatty acids in the diet were each significantly associated with lower SBP ( $P < .001$  for each relationship) and DBP ( $P < .001$  for each relationship) [187].

A randomized crossover trial investigated the effects on BP of a diet enriched with MUFA [provided as extra-virgin olive oil (EVOO)] and PUFA (provided as sunflower oil) [188]. Total 23 hypertensive patients with BPs  $<165/104$  mmHg and without end-organ damage were assigned to either an MUFA-rich or a PUFA-rich diet for 6 months. The diets were similar with regard to the daily content of protein, carbohydrates, total and saturated lipids, cholesterol, and fiber and differed only in the amounts of MUFA and PUFA. After eating one diet for the first 6 months, the participants were instructed to ingest the other diet for 6 more months. The ratios of the quantity of MUFA to PUFA in the MUFA and PUFA diets were  $5.7 \pm 2.6$  (mean  $\pm$  SD) and  $1.1 \pm 0.6$ , respectively. At the end of each study period, the participants allocated to the MUFA diet, as compared to the PUFA diet, exhibited significantly lower SBP ( $127 \pm 14$  vs  $135 \pm 13$  mmHg,  $P < .05$ ) and in DBP ( $84 \pm 8$  vs  $90 \pm 8$  mmHg,  $P < .01$ ). BP was controlled in eight

participants without antihypertensive medications during the MUFA diet, but in no participant during the PUFA diet. Moreover, the daily dosage of antihypertensive medications was significantly reduced during the MUFA diet, by 48% versus by only 4% during the PUFA diet (MUFA vs PUFA,  $P = .005$ ) [188].

The observational Chicago Western Electric Study analyzed, in a cohort of 1714 men, the relationship of the dietary intake of a large number of nutrients to the annual changes in SBP and DBP [189]. Dietary nutrient intake was analyzed in detail on two occasions separated by 1 year at the beginning of the study, and participants were followed for up to 8 years. When analyzed individually, MUFA intake, expressed as percent of total calorie intake, was positively related to changes in SBP and DBP during this multiyear period of observation. PUFA intake, expressed as a percent of total saturated fatty acids, was positively only related to changes in DBP. However, when analyzed as part of a composite of the other nutrient intakes that were examined, almost all of these associations disappeared. The cause of the difference between these findings and the other studies of MUFA reported earlier may be the source of MUFA; in the United States and Northern Europe, the main source of MUFA is meat, and the amount of MUFA intake is highly correlated with the intake of saturated fatty acids [190]. The study design, in which nutrient intake was only assessed twice in each participant, who was followed for up to 8 years, may also limit the reliability of the findings. Please also refer to the "Effect of dietary sources of fuel on blood pressure" section.

The relationship to BP to another class of ingredients in olive oil, phenolic compounds, has also been investigated. A network metaanalysis investigated the effects of different types of olive oil on serum lipid profiles and BP [191]. The types of olive oil investigated, which were refined olive oil, mixed olive oil, low-phenolic (extra) virgin olive oil, and high phenolic (extra) virgin olive oil, contained different quantities of phenolic compounds. Total 13 randomized controlled trials involving 611 mainly healthy participants were included in this metaanalysis. The duration of treatment in these trials lasted from 3 to 12 weeks. The metaanalysis indicated that SBP, but not DBP, was significantly lower when participants ingested olive oil preparations with higher as compared to smaller quantities of phenolic compounds. The participants taking the low-phenolic (extra) virgin olive oil, which contained <200 mg phenolic compounds/kg of olive oil, as compared to the participants taking refined olive oil, from which most bioactive and antioxidant compounds, such as polyphenols and tocopherols, were removed during the refining process, demonstrated a significantly lower SBP (mean difference between the

two groups,  $-2.87$  mmHg; 95% CI,  $-5.39, -0.35$ ). The group taking high phenolic (extra) virgin olive oil which contained 200 mg or more of phenolic compounds per kg olive oil manifested a nonsignificant tendency toward a reduction in SBP as compared to the participants taking the refined olive oil (mean difference,  $-2.99$  mmHg; 95% CI,  $-6.12, 0.15$ ). Moreover, the metaanalysis indicated that a daily dose of 5 or more mg/day of phenolic compounds in olive oil was associated with a significantly lower SBP (mean difference,  $-2.91$  mmHg; 95% CI,  $-5.04, -0.79$ ) as compared to a daily intake of <1 mg/day of phenolic compounds [191].

Another metaanalysis of eight randomized controlled trials investigated the differences in cardiovascular biomarkers between high- and low phenolic olive oil [192]. SBP was significantly lower in the group receiving high phenolic olive oil (mean difference,  $-0.52$ ; 95% CI,  $-0.77, -0.27$ ;  $P < .01$ ) as compared to the group taking low phenolic olive oil, whereas DBP was not different between the two groups (mean difference,  $-0.20$ ; 95% CI,  $-1.01, 0.62$ ;  $P = .64$ ). A randomized crossover trial investigated the effects of polyphenols in extra-virgin olive oil on BP [193]. The study recruited 24 young women with high-normal BP or stage 1 essential hypertension (SBP of 120–159 and DBP of 80–99 mmHg). They were fed both types of olive oil in a Mediterranean diet for 2 months each in a randomized crossover manner separated by a 4-week washout period. The participants were instructed to consume each day 60 mL of either polyphenol-rich or polyphenol-free olive oil; 60 mL of polyphenol-rich olive oil group provided about 30 mg/day of polyphenols. Both SBP and DBP significantly decreased from baseline with the polyphenol-rich olive oil. Changes in SBP were  $-7.91 \pm 9.51$  mmHg and  $-1.65 \pm 8.22$  mmHg ( $P < .001$ ) for the polyphenol-rich and polyphenol-free olive oil, respectively. DBP decreased by  $-6.65 \pm 6.63$  and  $-2.17 \pm 7.24$  mmHg ( $P < .001$ ) for polyphenol-rich and free olive oil, respectively. The magnitude of decrease in SBP and DBP was significantly greater in patients with higher baseline BP ( $P < .001$ ) [193].

The foregoing data indicate that phenolic compounds, polyphenol-rich olive oil, and possibly MUFA are ingredients in olives that may lower SBP and DBP in people with mildly elevated BP.

## Magnesium

Extracellular and intracellular magnesium ions inhibit calcium flux via the L-type  $\text{Ca}^{2+}$  channels in smooth muscle cells, which are the target of dihydropyridines, and thereby reduce muscle tone [194].

Moreover, the magnesium ion appears to suppress plasma aldosterone concentrations in humans [195]. Magnesium may also inhibit norepinephrine release from peripheral sympathetic nerve endings in spontaneously hypertensive rats by blocking calcium influx through N-type calcium channels [196]. Magnesium may exert its BP-lowering effects by decreasing intracellular sodium and cytoplasmic free calcium [197]. The combined intake of magnesium and taurine may lower SBP and DBP, possibly because both chemicals decrease intracellular calcium and sodium [197,198]. Therefore magnesium may potentially reduce BP by both direct and indirect actions on vascular smooth muscle cells.

Whether magnesium supplements per se lower BP in hypertensive individuals is controversial. Some studies show that magnesium reduces BP [199], whereas other studies do not [200]. The antihypertensive effects of magnesium supplementation are small in many of the studies that suggest such an effect. In one metaanalysis of 20 randomized clinical trials of magnesium supplementation in hypertensive persons (14 trials) and normotensive individuals (6 trials), 1220 persons were evaluated [199]. The dose of magnesium supplements ranged from 10 to 40 mmol/d with a median intake of 15.4 mmol/d. The pooled net estimates of BP changes with magnesium supplements showed only a small and statistically nonsignificant reduction in SBP,  $-0.6$  mmHg (95% CI,  $-2.2$  to  $+1.0$ ), and DBP,  $-0.8$  mmHg (95% CI,  $-2.1$  to  $+0.5$ ). There was no significant fall in SBP ( $P = .06$ ) or DBP ( $P = .17$ ) when the analysis was restricted to the 14 hypertensive trials. Nonetheless, this metaanalysis indicated a dose-dependent effect of magnesium on BP with an average reduction in SBP of  $-4.3$  mmHg (95% CI,  $-6.3$  to  $-2.2$ ,  $P < .001$ ) and in DBP of  $-2.3$  mmHg (95% CI,  $-4.9$  to  $-0.0$ ,  $P < .09$ ) for each 10 mmol/day (i.e.,  $\sim 243$  mg/day) increase in magnesium intake [199].

A more recent metaanalysis, including 34 randomized controlled trials and 2028 participants, but excluding people with active liver or kidney disease, demonstrated that magnesium supplements were associated with a significant reduction in SBP (weighted mean decrease,  $-2.00$  mmHg; 95% CI,  $-3.58$  to  $-0.43$ ) and DBP (weighted mean fall,  $-1.77$  mmHg, 95% CI,  $-2.82$  to  $-0.73$ ) [201]. The size of the dose and the duration of the magnesium supplements were related to the magnitude of reduction in BP. A higher dose ( $> 300$ -mg Mg/day) and longer duration of treatment ( $> 60$  days) with the magnesium supplements increased serum magnesium levels and decreased BP significantly. Changes in serum magnesium were associated with a more robust reduction in DBP than in SBP, and only the reduction in DBP was statistically significant:  $-2.26$  mmHg/ $0.1$  mmol/L increment in serum magnesium (95% CI,  $-4.26$  to  $-0.27$ ) [201].

Larger intakes of magnesium, that is, 500–1000 mg/day, may be more likely to lower BP [202]. A metaanalysis of nine cohort studies, including 180,566 participants with 20,119 hypertensive patients, found an inverse association between dietary magnesium intake and the risk of hypertension [relative risk (RR): 0.92; 95% CI, 0.86–0.98] comparing the groups with the highest intakes to the groups with lowest intakes. The same study demonstrated a 5% reduction in the risk of hypertension for each 100 mg/day increment in magnesium intake (RR: 0.95; 95% CI, 0.90–1.00). On the other hand, serum magnesium concentrations were only marginally and negatively associated with the risk of hypertension in this study (RR: 0.91; 95% CI, 0.80–1.02) [203].

Many people with hypertension have CKD with reduced ability to excrete magnesium, and caution must be exercised in these individuals, because these persons may be at increased risk for hypermagnesemia if they ingest large magnesium supplements. It is suggested that a high magnesium intake may have a more pronounced BP-lowering effect when it is provided with a high potassium and low sodium intake [202].

## Protein and amino acids

Epidemiological studies indicate an inverse relationship between protein intake and BP [204]. A small number of clinical trials indicate that supplements of soybean protein may decrease SBP or DBP [204–206]. A larger randomized, double-blind, controlled trial was carried out in 302 adults in China in which subjects were assigned to receive either 40 g/day of supplemental soybean protein or 40 g/day of complex carbohydrates [205]. All participants had prehypertension or stage 1 hypertension with an initial untreated SBP of 130–159 mmHg and/or DBP of 80–99. During the 12 weeks of treatment, SBP and DBP fell in both groups but decreased significantly more in the soybean protein-treated group. The greater decrease in BP in the soybean protein-treated participants over the complex carbohydrate-treated group was by  $-4.31$  (95% CI,  $-6.51$  to  $-2.11$ ) mmHg systolic and  $-2.76$  (95% CI,  $-4.16$  to  $-1.35$ ) mmHg diastolic at 12 weeks of intervention. In a subgroup analysis, there were significantly greater decreases in SBP ( $-7.88$  mmHg) and DBP ( $-5.27$  mmHg) in the soybean protein versus the carbohydrate-treated subjects who had stage 1 hypertension [205]. The prehypertensive individuals showed a trend, not significant, for a reduction in SBP and DBP. This study did not examine whether it was the protein or the isoflavones in the soybean that reduced the BP.

Another randomized crossover study investigated the effects on BP of increased protein intake [207]. The

participants were allocated to three groups that each received a supplement. One group received 40 g/day of a supplement of soy protein; the second group received 40 g/day of milk protein. The third group received a supplement of 50 g/day of complex carbohydrates without protein. The patients displayed a statistically significant reduction in SBP only when they ingested either the soy protein or milk protein. The changes in SBP (mmHg) were  $-1.5$  (95% CI,  $-2.4$ ,  $-0.6$ ),  $-1.8$  (95% CI,  $-2.8$ ,  $-1.0$ ), and  $0.5$  (95% CI,  $-0.4$ ,  $1.3$ ), respectively, with the soy protein, milk protein, and carbohydrate supplements ( $P$ -value for significance among the three groups:  $<0.001$ ). Nonsignificant decreases in DBP were also demonstrated with both the soy protein and the milk protein groups ( $P$ -value between groups:  $0.27$ ) [207]. A meta-analysis, including 27 randomized controlled trials, was performed to investigate the effect of soya bean supplements on BP [208]. Many of these trials were of small size. The study demonstrated significant decreases in both SBP (weighted mean difference  $-2.21$ ; 95% CI,  $-4.10$ ,  $-0.33$  mmHg,  $P = .021$ ) and DBP ( $-1.44$ ; 95% CI,  $-2.56$ ,  $-0.31$  mmHg,  $P = .012$ ). The metaregression analysis of these trials indicated that the BP-lowering effects of the soya supplements were larger in the studies with higher mean pretreatment BPs [208].

Several potential mechanisms have been suggested to explain how soybean protein may reduce BP [205]. Soybean protein contains substantial amounts of arginine, which can be converted to nitric oxide, a potent vasodilator [209]. Intravenous injection of arginine reduces peripheral vascular resistance and decreases BP in humans [210]. Glutamic acid, which is high in vegetable proteins, may have special BP-lowering effects [211]. Digestion of proteins derived from foods may release bioactive peptides that inhibit the ACE and that probably have other antihypertensive actions [212]. Milk proteins are particularly likely to yield these peptides [212]. This might contribute to the antihypertensive effects of the DASH diet (see later). Protein may also increase urinary excretion of sodium, water, and free dopamine [213,214]. A dopamine-mediated natriuresis engendered by ingested protein may lower BP [214]. Soybean protein may increase insulin sensitivity and glucose tolerance [215]; since insulin resistance and consequent hyperinsulinemia may predispose to hypertension (see earlier), this latter effect of soybean protein may decrease BP [216]. Soybeans contain bioactive polyphenolic compounds or isoflavones. These compounds can reduce BP by increasing the production of nitric oxide, and also by modulating the activities of potassium or calcium channels [217].

An epidemiological study of 3588 Dutch adults followed for up to 10 years reported that greater ingestion of grain protein was associated with a small

decrease in the incidence of hypertension; HR =  $0.85$ ; 95% CI,  $0.73$ – $1.00$ ;  $P_{\text{trend}} = .04$  for the risk of new-onset hypertension between the upper and lower tertiles of protein intake from grain [218]. The effect of protein intake on BP was confirmed by a metaanalysis of 40 randomized controlled trials with 3277 participants. The sources of protein were from animals (meat, fish, and dairy products), vegetables (including but not limited to soy), and mixed (animal and vegetable proteins combined) [219]. This study demonstrated that increased protein intake was associated with lower SBP (weighted mean difference,  $-1.76$ ; 95% CI,  $-2.33$ ,  $-1.20$  mmHg) and DBP ( $-1.15$  mmHg; 95% CI,  $-1.59$ ,  $-0.71$ ) compared an increase in carbohydrate or lipid intake. Plant protein and animal protein both lowered SBP and DBP significantly and to similar degrees [219]. Notwithstanding the modest BP-lowering effects of protein supplements, large protein intakes may not be indicated for many individuals who have diseases that render them protein intolerant, such as CKD, acute kidney injury, or liver failure.

## Fiber

Dietary fiber is considered part of a healthy diet that may exert protective effects on the gastrointestinal tract and cardiovascular system. Stroppel and coworkers carried out a metaanalysis showing that increasing dietary fiber intake in Western populations, where the usual fiber intake is well below recommended levels, may help to prevent hypertension [220]. In another metaanalysis, Whelton and coworkers reported that increased intake of dietary fiber may reduce BP in hypertensive patients; in normotensive individuals, there was no reduction in BP [216]. A recent extensive metaanalysis of both observational and interventional studies, involving 135 million person-years, investigated the effect of fiber intake on health-related outcomes, including changes in body weight, hemoglobin A1c (HbA1c), serum total cholesterol, and BP. This study also demonstrated that higher dietary fiber intake was significantly associated with decreased SBP (mean difference,  $-1.27$  mmHg; 95% CI,  $-2.50$ ,  $-0.04$ ) [221].

A randomized controlled trial in hypertensive individuals indicated that dietary protein and fiber has significant, additive effects on lowering both 24-hour and awake SBP [206]. It is possible that some of the antihypertensive effects of dietary sodium restriction may involve changes in the intake of other nutrients such as fiber. Sciarrone and associates report that reduction in sodium intake may decrease the dietary content of both fats and fiber, which might independently affect BP and lipid metabolism [222]. In a more recent, rather small-scale study lasting 12 weeks, overweight and

obese adults were randomly assigned to ingest their usual diet with placebo (the control group), their usual diet with 21 g/day of a psyllium fiber supplement, or a healthy diet with placebo [223]. The fiber intake of the participants assigned to the healthy diet, which did not include a fiber supplement, was evaluated at weeks 6 and 12. At these two times the actual fiber intake with the healthy diet exceeded the fiber intake in the usual control diet (without the fiber supplement) by 11.9 and 11.0 g/day, respectively. However, this increase in fiber intake with the healthy diet at weeks 6 and 12 was not as great as with the psyllium fiber supplement, which was 18.4 and 20.6 g/day at these two times [223]. In the subjects who completed the 12-week study, those who were fed the psyllium supplement, in comparison to the people fed the control diet, manifested a lower SBP and DBP only at 6 weeks ( $P = .04$  and  $.04$ , respectively), whereas the group fed the healthy diet with increased fiber showed a lower SBP only at 12 weeks and a lower DBP only at 6 weeks ( $P = .02$  and  $.04$ , respectively). Hence, this latter study did not provide evidence of an important BP-lowering effect of psyllium fiber.

## Alcohol

Excessive alcohol intake often increases BP. However, these effects are generally transient, and BP usually falls rapidly when individuals stop drinking alcohol [224]. A time-dependent association between alcohol consumption and BP levels was reported by Moreira in experimental studies of free-living individuals. In contrast, in another study the frequency of alcohol consumption and type of beverage ingested were not found to be independently associated with BP levels [225].

African-American subjects who consumed large amounts of alcohol showed a high risk of developing hypertension [226]. Consumption of low-to-moderate amounts appears to be associated with a higher risk of hypertension in black men but not in white men or black or white women [227]. Also, in Chinese males, a higher intake of alcohol is associated with a higher risk for isolated systolic hypertension, both systolic and diastolic hypertension, and isolated diastolic hypertension [228]. In the North American free-living population, the consumption of alcohol in amounts  $>210$  g/week is reported to be an independent risk factor for hypertension [227]. In hypertensive individuals, heavy alcohol consumption leads to a significant increase in the risk of cerebral hemorrhage, suggesting a synergistic effect of alcohol and hypertension [229]. On the other hand, light alcohol consumption significantly reduces the risk of ischemic stroke [230].

Metaanalyses indicate that a gender difference exists between the association of the amount of alcohol consumed and the prevalence of hypertension [231,232]. In men, there was a linear, dose-dependent relationship between alcohol consumed and hypertension. In women a modest alcohol intake (less than 10 g/day) was associated with an attenuation in the prevalence of hypertension, though alcohol intake of 30 g/day or more was significantly associated with a higher prevalence of hypertension [232]. Hence, a J-curve association between alcohol intake and the risk of hypertension was observed in women, whereas a linear association was observed in men [231,232]. The mechanism for this gender difference is unclear [231,232]. Of interest a Japanese cohort study conducted for 10 years that involved 123,764 participants found that ethanol intake of  $<20$  g/day was associated with a lower incidence of hypertension or new onset of stage 3 or more severe CKD [233]. This association was significant in men (HR 0.86; 95% CI, 0.78–0.95) but marginal in women (HR 0.80; 95% CI, 0.63–1.02) [233].

The mechanisms involved in alcohol-generated hypertension appear to include the upregulation of the central or peripheral SNS, activation of the renin–angiotensin system, attenuation of baroreceptor activity, increase in calcium within vascular smooth muscle cells, and endothelium dysfunction characterized by a decrease in NO production and an increase in endothelin production [234,235]. Zilkens and coworkers studied 24 healthy men who underwent four interventions, in random order, for 4 weeks each [236]: (1) abstinence from all alcohol and grape products; (2) an intake of 375 mL per day of red wine containing 39-g alcohol; (3) an intake of 375 mL per day of dealcoholized red wine; or (4) an intake of 1125 mL per day of beer providing 41-g alcohol. Daily consumption of about 40 g of alcohol either as red wine or beer resulted in a similar mild increase in 24-hour SBP and awake SBP and 24-hour heart rate, whereas dealcoholized red wine did not lower BP. The red wine, beer, and dealcoholized red wine did not affect vascular function (i.e., flow-mediated vasodilation). These observations suggest that in men it is the alcohol in red wine and beer that increases SBP, and that nonalcoholic components of red wine do not mitigate the BP-elevating effects of alcohol [236]. One metaanalysis indicated that the reduction of alcohol consumption in those who regularly take three or more drinks per day resulted in a significant decrease in both SBP and DBP. These findings reinforce the thesis that large intakes of alcohol increase BP [237]. Notwithstanding evidence that alcohol, particularly in larger amounts, is associated with increased BP, there are abundant epidemiological data indicating that alcoholic drinks, and possibly particularly red wine, may reduce the risk of death from cardiovascular disease. The mechanisms

for this protective effect are not completely understood and may involve the actions of alcohol per se and possibly also the effects of the antioxidant and vasodilator phenolic compounds.

## Vitamin D

Vitamin D deficiency (deficiency of 25-hydroxy cholecalciferol [25(OH)D]) is reported to occur commonly throughout the world, especially in Asia, the Middle East, and Africa [238–240]. In low- and lower middle-income countries, almost 50% of the population is reported to exhibit serum 25(OH)D below 25 nmol/L [240]. Vitamin D *insufficiency* is often defined as a serum 25(OH)D concentration of 20–30 ng/mL (50–75 nmol/L), and vitamin D *deficiency* is defined as 25(OH)D level below 20 ng/mL (<50 nmol/L) [238]. Approximately 80%–90% of the body's vitamin D levels are considered to come from the effects of sunlight on the skin [238], and the high risk of vitamin D deficiency is considered to be due to reduced outdoor activities, efforts to avoid sun exposure, air pollutants, living at high latitudes, dark skin, frequent use of sunscreens, protective clothing against the sun, and the impaired ability of older people to produce vitamin D in the skin in response to sunlight.

Knockout mice for the vitamin D receptor or the 1 $\alpha$ -hydroxylase enzyme develop high renin hypertension and cardiac hypertrophy [241,242]. In hypertensive patients, there may be an inverse relationship between PRA and serum 1,25(OH)<sub>2</sub>D levels [243]. Studies at the cellular and molecular levels indicate that 1,25(OH)<sub>2</sub>D is a negative regulator of renin gene expression due to the binding of the vitamin D receptor to the transcription factor cyclic adenosine monophosphate-response element-binding protein [244].

1,25(OH)<sub>2</sub>D also suppresses vascular endothelial and smooth muscle cell tissue factor, thrombospondin, and plasminogen activator inhibitor-1 and increases the synthesis of vascular endothelial growth factor, prostaglandin, and hepatic thrombomodulin [245]. These effects would appear to be cardioprotective, inhibitory of thrombosis, and promotive of fibrinolysis [245,246].

Epidemiological and other studies also suggest that, in addition to bone mineral and divalent ion metabolism, vitamin D may also reduce insulin resistance and have vascular protective, renoprotective, and antiinflammatory effects [247–250]. Hence, vitamin D may not only reduce BP but may also prevent or ameliorate a number of vascular and renal complications of hypertension. On the other hand, excessive vitamin D intake with toxicity [e.g., serum 25(OH)D >150 ng/mL (>374.4 nmol/L)] may induce hypercalcemia, arterial stiffness, hypertension, and progressive renal failure [238].

Some, but not all cross-sectional epidemiological studies describe an inverse relation between serum 1,25(OH)<sub>2</sub>D and especially 25(OH)D levels and SBP or DBP [245,246]. Clinical trials of vitamin D supplementation on BP also are not consistent. One double-blind trial of 1200-mg calcium/day alone or with cholecalciferol of 800 IU/day in elderly vitamin D deficient women showed significant reductions in SBP and DBP in both groups, but with a significantly greater reduction in SBP in the vitamin D–treated group ( $P = .02$ ) [251]. Most, but not all, of the other trials of vitamin D supplements on SBP or DBP were negative [246]. A metaanalysis, including 17 randomized control trials and 1687 participants, reported that oral vitamin D<sub>3</sub> did not have a significant effect on BP in vitamin D–deficient people, although oral vitamin D<sub>3</sub> was associated with a reduction in SBP in people who were both vitamin D deficient and either more than 50 years old, obese (BMI  $\geq 30$  kg/m<sup>2</sup>) or hypertensive [252].

It has been argued that most of these studies were not primarily or adequately designed to assess the effects of vitamin D on BP; the subjects were not hypertensive or vitamin D deficient; the vitamin D dose might have been too low (e.g., 400 IU/day) or the BPs may not have been measured in a sophisticated fashion [246]. An example is the Women's Health Initiative (WHI) which conducted the largest randomized clinical trial of vitamin D [253]. This trial, which was carried out for a mean of 7 years, randomized over 32,000 postmenopausal women to receive 400 IU vitamin D plus 1000-mg calcium/day or placebo. Although there were no significant differences in changes in SBP or DBP or in the incidence of hypertension during the study, it is possible that the vitamin D dose was too small.

A randomized controlled trial investigated the effects of providing cholecalciferol, 50,000 IU/week, for 8 weeks to patients with essential hypertension and reduced plasma vitamin D levels [25(OH)D < 30 ng/mL]. In the patients receiving the vitamin D supplements, PRA decreased from  $1.51 \pm 0.4$  to  $1.17 \pm 0.3$  ng/mL/hour,  $P = .02$ , and plasma angiotensin II fell from  $15.8 \pm 2.7$  to  $11.6 \pm 1.6$  pg/mL,  $P = .02$ . However, endothelial function, measured by flow-mediated dilatation of the radial artery, did not improve in the treatment group. BP also did not decrease after the administration of vitamin D in the hypovitaminosis D patients [254]. In another double-blind, randomized controlled trial of overweight patients with vitamin D deficiency, ergocalciferol 50,000 IU/week did not reduce renin–angiotensin system activity or BP [255]. However, these patients did not have hypertension.

Supplementation with 1,25(OH)<sub>2</sub>D or its analogs, paricalcitol or 1 $\alpha$ -hydroxyvitamin D, has also given inconsistent results with regard to BP reduction [246]. The PRIMO Trial studied 115 patients with stage 3 or 4 CKD,

left ventricular hypertrophy, and preserved left ventricular ejection fraction who were randomized to receive paricalcitol, 2.0 µg/day, and 112 similar patients randomized to placebo for up to 48 weeks [256]. The paricalcitol dose could be reduced to 1 µg/day if patients became hypercalcemic. Of patients, 96% were hypertensive. SBP or DBP did not differ significantly during the course of the study. More well designed, adequately powered randomized controlled clinical trials are needed to definitively assess the possible effects of vitamin D on BP.

Ultraviolet radiation increases the endogenous vitamin D. Exposure to ultraviolet B radiation for 12 weeks did not change BP compared to ultraviolet A radiation, although the mean 25(OH)D levels increased in the group irradiated by ultraviolet B [257]. On the other hand, an epidemiological study of 1410 Chinese residents in Macau revealed that the amount of habitual sunlight exposure each day was negatively associated with the presence of hypertension, and that sun exposure for more than half an hour per day was associated less with hypertension (OR 0.6, 95% CI, 0.4–0.8) [258].

## Chocolate

A randomized, crossover, short-term (7-day) study was conducted to assess the effect of chocolate ingestion on BP in 20 patients with grade I essential hypertension who had never received antihypertensive treatment [259]. Eating dark chocolate, but not white chocolate, was associated with a significant lowering of SBP ( $-11.9 \pm \text{SD } 9.7$  mmHg,  $P < .0001$ ) and DBP ( $-8.1 \pm 5.0$  mmHg,  $P < .0001$ ). The authors suggest that dark chocolate may lower BP by its high content of flavonols that induce vasorelaxation. Dark chocolate has also been shown to decrease isolated systolic hypertension in geriatric patients [260] and, in one [261] but not in all studies [262], in healthy persons. Hypertensive patients who took a combination of antihypertensive medicines and flavonoids from dark chocolate, dried red apples, and green tea displayed a greater decrease in both SBP and DBP as compared to those who took antihypertensive drugs alone [263].

The possible antihypertensive effects of chocolate or its cocoa product were investigated by several metaanalyses [264–266]. These studies demonstrated that both SBP and DBP decreased after intake of chocolate or cocoa products. One metaanalysis provided evidence that cocoa or chocolate intake was associated with a reduction in SBP and DBP of  $-1.76$  (95% CI,  $-3.09, -0.43$ ) mmHg, and  $-1.76$  (95% CI,  $-2.57, -0.94$ ) mmHg, respectively. These BP-lowering effects of chocolate or cocoa were more evident among the patients with higher baseline BP measurements [266].

Another study indicated that the intake of flavonol-rich chocolate or dark chocolate, in contrast to white chocolate or low-flavonol chocolate, was associated with improvement in the insulin resistance index and fasting insulin levels [265].

## Coffee and caffeine

Suzuki et al. showed hypotensive effects of green coffee bean extract and its metabolites in spontaneously hypertensive rats [267]. Kozuma et al. reported a dose-responsive antihypertensive effect of green coffee bean extract given to mildly hypertensive individuals for 28 days [268]. These findings were confirmed by Watanabe and coworkers who studied essential hypertension in rats and humans [269]. The BP-lowering effect of green coffee bean extract is attributed to the effects of chlorogenic acid, a biologically active dietary polyphenol, and its metabolites on vascular reactivity [267–270].

Interestingly, the roasted-coffee extract may not have these antihypertensive effects [267], possibly because chlorogenic acid is easily degraded by heat. Caffeine induces fluctuations in BP by stimulating not well-specified cardiovascular mechanisms [271]. Corti studied the acute effects of coffee in volunteers who drank a triple espresso or a decaffeinated triple Espresso or who were infused intravenously with 250 mg of caffeine. The subjects, who were nonhabitual coffee drinkers, showed an increase in sympathetic nerve activity, measured by microneurography in muscle, and a rise in BP after receiving the coffee which was independent of whether caffeine was present [272]. A clinical trial demonstrated that two cups of coffee (600 mL total) were associated with an elevation in BP and mitigation of the BP-lowering effects of the calcium channel blocker felodipine on both brachial and aortic BP that lasted for up to 8 hours [273]. The mean differences in brachial artery SBP and DBP with coffee plus felodipine versus felodipine without coffee were 3.8 (95% CI, 1.1, 6.4) and 1.5 (95% CI, 0.2, 2.8) mmHg, respectively, during the 5–8 hours after coffee ingestion. These results indicate the amount of coffee ingested and the time after its consumption that might be taken into consideration when assessing its possible effects on BP measurements in hypertensive patients [273].

An acute effect of caffeine on BP in hypertensive patients was confirmed by a metaanalysis, which demonstrated that SBP increased by 8.14 mmHg (95% CI 5.68, 10.61) for up to 180 minutes after ingestion of 200–300 mg of caffeine [274]. Consumption of either sugar-containing or diet cola beverages has also been associated with increased risk for hypertension,

possibly due to its caffeine content [275]. Thus the foregoing studies suggest that both coffee with or without caffeine and caffeine alone can each independently increase BP.

On the other hand, the chronic effects of coffee consumption on BP are somewhat different from the acute effects described earlier and are often conflicting. A metaanalysis of 11 interventional trials of coffee drinking, 10 of which were randomized and controlled, which encompassed the controlled studies published between 1983 and 1994, demonstrated that coffee consumption increased SBP and DBP by 2.4 (range, 1.0–3.7) and 1.2 (range, 0.4–2.1) mmHg, respectively [276]. The population of the studies included in this metaanalysis was relatively young (median age, 38 years old), was studied for a short duration of time (median duration, 56 days), and was normotensive at baseline (median values of average BP, 119/71 mmHg). However, another metaanalysis, including both randomized controlled trials and cohort studies, indicated that coffee consumption did not significantly affect either BP or the incidence of hypertension [277]. A number of the studies in this metaanalysis were considered to have low-quality evidence. Moreover, two other dose–response metaanalyses of cohort studies of coffee intake indicated that consumption of many cups of coffee, that is, more than six cups per day, was associated with a lower incidence of hypertension [278,279]. The risks of incident hypertension were 0.99 (95% CI, 0.98–1.00) [278] and 0.98 (95% CI, 0.98–0.99) [279], respectively, in these two studies.

## Pregnancy

The effect of coffee or tea intake on BP in pregnant women is controversial. A cohort study of 7890 pregnant women [280] found that high coffee or tea intake was associated with higher SBP in the first and third trimesters (*P* for trend .014 and .009, respectively) but not in the second trimester (*P* for trend .441), whereas higher coffee or tea intake was not associated with DBP in any trimester. The authors ascribe these effects on SBP to the high caffeine content in these drinks [90 mg of caffeine (equal to 1 unit) in a 125-mL cup of regular coffee and 45 mg of caffeine (equal to 0.5 unit) in a regular cup of tea.]. The analyses appear to be adjusted for the intake of decaffeinated coffee and tea. Interestingly, women imbibing a caffeine intake from coffee of 180 to about 350-mg caffeine/day from coffee or tea appeared to have a lower incidence of preeclampsia than women drinking <180-mg caffeine/day from coffee or tea (OR: 0.63, 95% CI 0.40, 0.96) [280].

A case-crossover design study that involved 286 pregnant women with preeclampsia found that the frequency of caffeine exposure from coffee, tea, and colas

was inversely associated with the risk of preeclampsia [281]. The patients completed a questionnaire regarding their medical history, current health, and recent activities. The frequency at which coffee, tea or colas, spicy food, and alcohol were consumed during the 7 days before presenting with preeclampsia, as compared to the week before, was each associated with a lower incidence of preeclampsia (for caffeine, OR 0.51, 95% CI 0.33, 0.77) [281]. Another prospective multicenter case–control study in Ethiopia had different findings. This study investigated factors, including coffee intake, that were associated with the incidence of preeclampsia [282]. The cases studied were pregnant women diagnosed with preeclampsia or eclampsia either during a prenatal clinic visit or when they presented to the facility in labor. Controls were normotensive women delivered in the same facilities at the same time as the patients with preeclampsia or eclampsia. After adjustment for covariates, daily coffee intake was associated with higher incidence of preeclampsia or eclampsia (OR 1.78, 95% CI 1.20, 3.05) [282].

## Tea

The relationship between BP and tea drinking is particularly relevant, because the volume of tea consumption is second only to water intake in the world [283]. The effect of tea on BP may be less consistent than the effects of coffee according to different reports [284]. However, Yang and coworkers report that chronic consumers of moderate amounts of green or oolong tea are less likely to develop hypertension [285]. This effect may be due to flavonoids, which affect endothelial function [286]. Green, oolong, and black tea contain a number of flavonoids and other compounds that, in animal and human studies, engender vasodilatation, protect against endothelial dysfunction, and have antioxidant, antiinflammatory, or hypolipidemic effects [283,287,288]. Grassi et al. investigated the effect of 150 mg of tea flavonoids twice daily for 8 days on endothelial function and circulating angiogenic cells. They found that ingestion of tea flavonoids increased flow-mediated dilatation and endothelial progenitor cells [289]. However, in another double-blind study, normal subjects were studied twice, once after they drank three cups of black tea which contain about 400 mg of flavonoids and once after drinking a similar-appearing placebo [290]. The black tea did not appear to affect endothelial function, since the resistance to forearm arterial blood flow in response to several vasodilators was not different when the subjects drank black tea as compared to placebo.

Hodgson et al. showed that consumption of foods altered the acute beneficial effects of tea on BP in humans [291]. A meal ingested with tea blunted the

BP-lowering effect of tea; the decrease in SBP with tea was smaller when it was ingested with meals, whereas flow-mediated dilatation was not changed by tea intake with or without meals.

A controlled trial was conducted in 95 regular tea drinkers who were randomized to drink three cups/day of black tea or placebo for 6 months [292]. Mean 24-hour baseline SBP and DBP were 121.4 and 72.9 mmHg, respectively. Compared with placebo, at 6 months, the black tea drinkers sustained a significant decrease in 24-hour ambulatory SBP ( $-2.0$  mmHg,  $P = .05$ ) and DBP ( $-2.1$  mmHg,  $P = .003$ ). The 24-hour ambulatory SBP and DBP were also significantly lower in the black tea--drinking participants at 3 months [292]. Similarly, another trial investigated the BP-lowering effect of green tea extract in obese prehypertensive women. This study showed that green tea extract intake for 4 weeks significantly reduced 24-hour, daytime, and nighttime BP measured by ambulatory BP monitoring [293]. Several metaanalyses have investigated the effects of tea drinking on BP. A metaanalysis on green tea drinking demonstrated reductions of SBP and DBP by  $-2.05$  (95% CI,  $-3.06, -1.05$ ) and  $-1.71$  (95% CI,  $-2.86, -0.56$ ) mmHg, respectively [294]. A metaanalysis on black tea drinking also revealed decreases in both SBP and DBP by  $-1.8$  (95% CI,  $-2.8, -0.7$ ) and  $-1.3$  (95% CI,  $-1.8, -0.8$ ), respectively [295]. Sour tea (*Hibiscus sabdariffa* L.) is also known to reduce BP. A metaanalysis demonstrated that sour tea was associated with a decrease in both SBP (by  $-7.58$  mmHg; 95% CI,  $-9.69, -5.46$ ) and DBP (by  $-3.53$  mmHg; 95% CI,  $-5.16, -1.86$ ), although there was large heterogeneity in the results [296]. Taken together, these studies suggest that tea intake may acutely decrease BP and may or may not affect endothelial function. Consuming tea with food may attenuate the BP-lowering effect but chronic intake of green, black or oolong tea is likely to decrease BP.

## Urate

As indicated in the previous discussion on obesity, elevated serum urate levels may predispose to hypertension. Metaanalyses that examined the association of hyperuricemia with incident hypertension [297] and prehypertension [298] showed that patients with hyperuricemia are more likely to develop prehypertension or hypertension. The risk ratio for hypertension in patients with hyperuricemia was 1.48 (95% CI, 1.33, 1.63) and 1.15 (95% CI, 1.06, 1.26) for each 1 mg/dL increase in serum uric acid levels [297].

In a double-blind, placebo-controlled, crossover trial in adolescents with newly diagnosed stage 1 essential hypertension and with serum urate levels of 6.0 mg/dL or greater, short-term treatment with allopurinol, which

decreased serum urate levels, lowered BP [296]. Of the 30 participants in this study, 22 were overweight or obese. A metaanalysis of the effect of allopurinol on BP reduction in hyperuricemic patients who did or did not have hypertension demonstrated a small but significant decrease in both SBP,  $-0.321$  mmHg (95% CI,  $-0.497, -0.145$ ,  $P < .001$ ), and DBP,  $-0.260$  mmHg (95% CI,  $-0.102, -0.417$ ,  $P = .001$ ) [299]. Fructose intake predisposes to urate formation, and as indicated earlier, fructose intake is directly correlated with SBP and DBP in people with higher urinary sodium excretion [54].

## Dietary, surgical, and lifestyle strategies to prevent or treat hypertension

In addition to increasing or reducing the intake of nutrients that may affect BP, which are reviewed earlier, specific preventive and therapeutic nutrition-related strategies have been developed to prevent or treat hypertension. These strategies involve dietary management, surgical procedures, and lifestyle changes, and they will be discussed in the following sections. Methods for the prevention of excessive fat gain and weight reduction treatments utilizing healthy lifestyles and reduced energy intake or bariatric surgery are discussed in Chapters 40–42. The following comments briefly summarize these approaches, particularly with regard to the prevention or treatment of hypertension.

### Bariatric surgery

Weight reduction by dietary intervention or bariatric surgery in obese, hypertensive persons, with or without diabetes mellitus or CKD, is now widely performed and is generally associated with a decrease in BP [300]. Programs have been designed to lower dietary energy intakes, fat mass, and BP and generally include a more global health-oriented approach that also emphasizes an overall healthier diet and lifestyle. These programs will be discussed later. The effects of medicine-induced weight loss on hypertension will also briefly discussed [57,301–303].

The clinical experience with bariatric surgery is discussed in detail in Chapter 41, Bariatric Surgery and Kidney Disease. In general, weight loss is substantially greater with bariatric surgery than with diet and lifestyle treatments (see later), particularly when the effectiveness of treatment is evaluated over periods of time measured in years rather than just a few months. Some types of bariatric surgery appear to be the most reliable and effective methods available for reducing fat mass in obese individuals, including patients with diabetes mellitus [66,300,304–306]. Reversal of type 2 diabetes

in obese individuals appears to be much more common with bariatric surgery than with diet and lifestyle changes alone [66,306] (Chapters 40–42). A metaanalysis of six randomized controlled studies indicated that bariatric surgery was strikingly more effective than the combination of medical treatment and attempted dietary interventions and lifestyle modifications for attaining a long-lasting remission of type 2 diabetes; the OR was 76.4 (95% CI, 20.7, 281.7) [307]. The same metaanalysis demonstrated that SBP was significantly lower in the bariatric surgery group than the medical treatment, dietary intervention, and lifestyle changes group (mean difference  $-2.83$  mmHg, 95% CI  $-4.88$ ,  $-0.78$ ,  $P < .01$ ), while DBP was not (mean difference  $0.28$  mmHg, 95% CI  $-1.89$ ,  $2.45$  mmHg,  $P = .80$ ) [307].

It should be emphasized that successful bariatric surgery programs also include counseling to reduce energy intake and to adopt a healthier lifestyle as well as the surgical procedure itself. After surgery the types and volumes of foods that can be ingested by the patient may need to be dramatically changed. Of the several types of bariatric surgery most commonly used, gastric banding and sleeve gastrectomy are less invasive than some of the other procedures employed, and the incidence of serious complications tends to be lower. But weight loss may be greater and more sustained with the more extensive types of surgery (see Chapter 41: Bariatric Surgery and Kidney Disease [66]). Overall, the complication rates with bariatric surgery are not high. Accumulating evidence suggests that the procedure has long-lasting effectiveness in both diabetic patients [308,309] and hypertensive patients [309]. Evidence from long-term follow-up suggests that weight loss, reduced glycemia, and cardiovascular risk may be sustained for 10 or more years after bariatric surgery [300,304,308]. Bariatric surgery is becoming an increasingly common option to attain long-term weight reduction for people who are refractory to weight reduction by dietary and lifestyle changes alone (please see Chapters 40–42).

## Health-enhancing diets and lifestyles

For over 30 years, there has been a growing focus on the use of complex, health-enhancing diets to prevent or treat hypertension, usually of the mild-to-moderately severe variety. The composition of these diets is generally based on evidence that the individual constituents of these diets have preventative or therapeutic effects on hypertension. Much of this evidence is summarized in the first part of this chapter. Experience regarding the effectiveness and patient adherence to these diets is discussed next.

## The hypertension prevention trial

The Hypertension Prevention Trial (HPT) was a multicenter trial in which 841 adults with DBPs of 78–89 mmHg were randomly assigned to one of four dietary counseling treatments (decreased energy intake, decreased sodium intake, decreased sodium and energy intake, or decreased sodium and increased potassium intake) or to a control group that did not receive dietary counseling [310]. Men and women with lower BMIs ( $n = 211$ ) were not assigned to the two low energy–intake groups. Subjects assigned to one of the four treatments underwent group counseling weekly for the first 10 weeks, then every other week for the next 4 weeks, and finally bimonthly for the duration of the study. Phone calls, newsletters, and other methods were employed to facilitate training and compliance. People were followed for 3 years. Attendance at scheduled counseling sessions declined significantly with time. At 6 months, overnight urine sodium excretion had fallen by 13%, urine potassium increased by 8%, and body weight fell by  $-7\%$  as compared to changes in the control group. At 3 years the reductions in urine sodium and body weight, compared to changes in controls, were  $-10\%$  and  $-4\%$ , respectively, whereas there was no change in urine potassium. The net reductions in weight in the low energy groups at 3 years were due, in large part, to the increase in weight in the control group. BP decreased from baseline in all treatment groups, including the controls. The largest net reduction in SBP and DBP occurred in the low energy group alone,  $-5.1$  and  $-2.4$  mmHg and  $-2.8$  and  $-1.8$  mmHg, at 6 months and 3 years, respectively ( $P < .05$  for each BP at each time). The sodium reduction groups sustained a significantly lower composite rate of hypertensive events (i.e., SBP  $\geq 140$  mmHg, DBP  $\geq 90$  mmHg or intake of antihypertensive medicines); the other treatment groups experienced a non-significant trend in this same direction.

## The trials of hypertension prevention: TOHP Phase I

The trials of hypertension prevention (TOHP) was a multicenter trial involving two phases. TOHP Phase I was a short-term trial designed to test the effect of three different lifestyle interventions and four nutritional supplements on BP control in individuals with high-normal DBP. TOHP Phase II was designed to test more long term, for 36–48 months, those interventions that were demonstrated in TOHP Phase I to lower BP. In Phase I, 2182 men and women with average high-normal DBP (80–89 mmHg) and with SBP  $\leq 160$  mmHg were randomized in a parallel-controlled fashion to receive either lifestyle modification or nutritional supplementation. The interventions undertaken in the life-style modification component of the study included weight

loss intervention, dietary sodium reduction, stress management, or usual care (UC). In the parallel nutritional supplement component of the study, nutritional supplements in the form of calcium or magnesium in stage 1 and fish oil or potassium in stage 2, as well as placebo, were given to the participants for 18 months [311,312]. The four nutritional supplements and the placebo were fed in a double-blind design. The nutritional supplements were fed in two stages, each of 6-month duration. In stage 1, participants were fed a supplement providing, each day, 1.0-g calcium, 360-mg magnesium or placebo. After a washout period, they entered stage 2, where they were rerandomized to be fed a supplement providing, each day, 6-g fish oil (containing 3.0-g omega-3 fatty acids), 60-mmol potassium or placebo. The weight loss, sodium reduction, and stress management groups underwent weekly group counseling sessions for 14, 10, and 8 weeks, respectively, and then at semimonthly or monthly intervals for the rest of the 18-month intervention.

In TOHP Phase I, in a comparison of baseline data to the final measurements, the weight reduction intervention produced a weight loss of  $-3.9$  kg ( $P < .01$ ) and a decrease in SBP of  $-2.9$  mmHg ( $P < .01$ ) and DBP of  $-2.3$  mmHg ( $P < .01$ ) [312]; the sodium reduction diet decreased urine sodium excretion by  $-44$  mmol ( $P < .01$ ), SBP by  $-1.7$  mmHg ( $P < .01$ ), and DBP by  $-2.9$  mmHg ( $P < .05$ ). There was no significant decrease in SBP or DBP between the baseline and final measurements with either stress management or the UC despite evidence for good compliance. Essentially similar results were observed for the lifestyle interventions at the 6-month follow-up, or for the nutritional supplements at the 3-month follow-up, except that DBP fell significantly at 3 months with the potassium supplement [312]. A posttrial follow-up evaluation 7 years later of 181 of the subjects indicated that the weight loss group and dietary sodium restriction group displayed a 77% and 35% decrease, respectively, in the OR of having hypertension [311].

### The trials of hypertension prevention: TOHP Phase II

TOHP Phase II tested whether weight loss, reduced sodium intake, or a combination of weight loss and reduced sodium intake will decrease DBP, SBP, or the incidence of hypertension (defined as DBP of 90 mmHg or greater, SBP 140 mmHg or greater, and/or the use of antihypertensive medications) in overweight or moderately obese individuals with high-normal DBP (83–89 mmHg) and SBP below 140 mmHg at entry into the study [313–316]. A total of 2382 men and women who were 110%–165% above desirable body weight were randomly assigned to these three treatment arms or to a UC

group in a two by two factorial design where they were assigned to weight loss or no weight loss and to sodium reduction or no sodium reduction. Subjects were followed for 3–4 years. Patients participated in group meetings and received individual counseling during this time, which initially was intensive and then became less frequent as the study progressed. Body weight, urinary sodium, and BP were measured every 6 months, and at 18 and 36 months, BP was measured over a series of three visits separated from each other by 7–10 days.

The participants who received the combination of weight loss and sodium reduction (the combined group) exhibited mean body weight loss of  $-4.1$ ,  $-2.2$ , and  $-0.3$  kg at 6, 18, and 36 months, respectively [314,315]. The UC group displayed a progressive weight gain that reached  $+1.8$  kg at 36 months. The decrease in weight in the weight loss groups, calculated as the difference between the weight change in the two weight loss groups combined and the weight change in the UC group, was significantly negative at each of these three time points. Mean SBP and DBP decreased by  $-6.2/-5.6$ ,  $-3.9/-4.5$ , and  $-0.5/-3.0$  mmHg, respectively, in the combined group at 6, 18, and 36 months. The reductions in SBP and DBP were each significantly greater in the two weight loss groups combined as compared to the UC group at these three time points.

Urinary sodium excretion decreased, on average, by  $-64.3$ ,  $-45.4$ , and  $-34.1$  mmol/day in the combined group at 6, 18, and 36 months, respectively. In the UC group, urinary sodium decreased by  $-27.6$ ,  $-16.8$ , and  $-10.5$  mmol/day at these three time points [314]. The fall in urinary sodium excretion in the two sodium reduction groups, calculated as the difference between the decrease in urinary sodium in the two sodium reduction groups combined, and the decrease in urinary sodium in the UC group, was significantly greater at 6, 18, and 36 months. The decrease in mean SBP and DBP in the combined group was  $-5.1/-4.4$ ,  $-3.8/-4.4$ , and  $-0.7/-3.0$  mmHg, respectively, at these three time points. In the two sodium reduction groups combined, as compared to the UC group, the reduction in SBP was significantly greater at all three time points, whereas the reduction in DBP was significantly greater only at 6 and 18 months.

Throughout the 48 months of the TOHP Phase II clinical trial, the incidence of hypertension, defined as SBP  $\geq 140$  mmHg or DBP  $\geq 90$  mmHg or the use of antihypertensive medicines, was less, and usually statistically significantly less, in the two weight loss groups combined, in the two sodium reduction groups combined and in the weight loss and sodium reduction intervention group as compared to the UC group (average relative risks, 0.78–0.82). Those subjects who displayed greater and sustained weight loss had the

greatest reduction in BP and the lowest risk ratio for hypertension. The effects of weight loss and decreased sodium chloride intake combined were not additive. After 6 months of treatment, the two interventions were less effective in maintaining both weight loss and low sodium intake, and, possibly for these reasons, the reduction in BP was also attenuated [314–316]. The results of the HPT, TOHP Phase I, and TOHP Phase II trials demonstrate that in overweight or moderately obese individuals, dietary modifications that reduce body weight and dietary sodium intake will reduce BP, but that weight loss, reduced sodium intake, and the decreased BP are difficult to sustain for 2–3 years or longer.

### The dietary approaches to stop hypertension diet

The DASH study provides much relevant information concerning appropriate dietary therapy to control BP [317]. The DASH study was a multicenter study that compared a “control” typical American diet (low in fruits, vegetables, dairy products, essential minerals, and fiber, and high in saturated and total fat) to a diet rich in fruits and vegetables and also to a combination diet rich in fruits, vegetables, and low-fat dairy products and with a reduced saturated and total fatty acid content. The study was conducted in 459 adults with a mean age of 44 years, SBPs <160 mmHg, and DBPs of 80–95 mmHg. About 65% of the study subjects were racial minorities, especially African-American.

The control diet was fed to all subjects for 3 weeks, and individuals were then randomly assigned to remain on this diet or to ingest the diet rich in fruits and vegetables or the combination diet for an additional 8 weeks. All meals were prepared for the participants in a research kitchen, and five meals per week were ingested on the study site. The study used food rather than nonfood sources of calcium. As can be seen from Table 37.4, the control “American” diet was low in calcium, potassium, and magnesium; the average daily intake of these three minerals was close to the 25th percentile of dietary consumption by the US population, whereas the daily intake of calcium, potassium, and magnesium in the other two diets was close to the 75th percentile in the United States. The sodium content of all diets was similar. Baseline SBPs and DBPs averaged  $131.3 \pm \text{SD } 10.8$  and  $84.7 \pm 4.7$  mmHg, respectively. Hence, many individuals had only high-normal or normal BPs.

After the subjects commenced their experimental diets, there was a rapid, significant, and sustained fall in SBP and DBP with both the fruits and vegetables diet and the combination diet, subsequently referred to as the DASH combination diet or simply the DASH diet [318]. SBP and DBP fell more with the fruits and vegetables diet than with the control diet, by  $-2.8$

**TABLE 37.4** Key Nutrients in the dietary approaches to stop hypertension (DASH) diet, fruits-and-vegetables diet and Western control diet<sup>a</sup>.

Nutrients	Western control diet	Fruits-and-vegetable diet	DASH diet
Fat (% of total kcal)	37	37	27
Saturated	16	16	6
Monounsaturated	13	13	13
Polyunsaturated	8	8	8
Carbohydrate (% of total kcal)	48	48	55
Protein (% of total kcal)	15	15	18
Cholesterol (mg/day)	300	300	150
Fiber (g/day)	9	31	31
Potassium (mg/day)	1700	4700	4700
Magnesium (mg/day)	165	500	500
Calcium (mg/day)	450	450	1240
Sodium (mg/day) <sup>b</sup>	3000 (130 mmol/day)	3000 (130 mmol/day)	3000 (130 mmol/day)

<sup>a</sup>Values are for diets designed to provide an energy level of 2100 kcal/day.

<sup>b</sup>For the DASH-Sodium Trial the prescribed daily sodium intakes were 150 mmol (high intake, 3.45 g), 100 mmol (intermediate intake, 2.30 g) and 50 mmol (low intake, 1.15 g) [318]. An intermediate or lower sodium intake is recommended.

Adapted from Appel LJ, et al. A clinical trial of the effects of dietary patterns on blood pressure. DASH Collaborative Research Group. *N Engl J Med* 1997;336:1117–24.

(97.5% CI,  $-4.7$  to  $-0.9$ ) mmHg ( $P < .001$ ) and  $-1.1$  (97.5% CI,  $-2.4$  to  $-0.3$ ) mmHg ( $P = .07$ ), respectively. SBP and DBP also decreased more with the combination diet than the fruits and vegetables diet, by  $-2.7$  (97.5% CI,  $-4.6$  to  $-0.9$ ) mmHg ( $P = .001$ ) and  $-1.9$  ( $-3.3$  to  $-0.6$ ) mmHg ( $P = .002$ ). These declines in BP with both experimental diets occurred within 2–3 weeks and essentially persisted throughout the rest of the 8-week study period. Thus this study indicates that a diet high in fruits and vegetables significantly reduces BP and that the addition of about three daily servings of dairy products, predominantly low-fat milk, in association with a reduced saturated and total fat intake, approximately doubled the degree of BP reduction observed with the fruits and vegetables diet.

A more recent study investigated the relationship between consuming a pattern of foods that was similar to the DASH diet and the development of end-stage renal disease (ESRD) in adults with hypertension and CKD stage 3 (estimated GFR 30–59 mL/min/1.73 m<sup>2</sup>). Participants in the National Health and Nutrition Examination Survey (NHANES) III project were the subjects of this investigation [319]. The results indicated

that, over a median follow-up period of 7.8 years, low accordance with the DASH diet was associated with an increased risk of ESRD in these people with moderate CKD and hypertension, especially if they were non-Hispanic Blacks and diabetics [319].

### **The DASH low-sodium diet**

It is noteworthy that the DASH diet was neither a low-sodium diet nor a weight-reduction diet. The DASH-Sodium Trial was, therefore carried out to examine whether a sodium-restricted intake would have an additional BP-lowering effect in people ingesting the DASH combination diet [318]. The DASH-Sodium Trial was a multicenter study in which three different dietary sodium intakes were prescribed: a high-sodium diet, 3.45-g Na/day—roughly a typical US sodium intake; an intermediate-sodium diet, 2.3-g Na/day—a currently recommended intake; and a low sodium intake, 1.15-g Na/day. A total of 412 individuals were studied in four clinical centers [318]. Acceptance criteria included adults 22 years or older who had average SBPs of 120–159 mmHg or who had DBPs of 80–95 mmHg. Subjects first underwent a 2-week run-in period with a high-sodium Western diet. They were then randomly assigned to the DASH combination diet or to the Western diet. Both diet groups were fed each of the three levels of sodium intake for 30 days each in a randomized crossover design [318]. The primary and secondary endpoints of the study were the SBPs and DBPs with the three different sodium intakes. Statistical analyses were performed by intention-to-treat methods.

The results indicated that with the control Western diet, the intermediate sodium intake, as compared to the high intake, was associated with a reduction in SBP of  $-2.1$  (95% CI,  $-3.4$  to  $-0.8$ ) mmHg ( $P < .001$ ) and a reduction in DBP of  $-1.1$  (95% CI,  $-1.9$  to  $-0.2$ ) mmHg ( $P < .01$ ). When those individuals fed the DASH diet were fed the intermediate-sodium diet, as compared to the high-sodium diet, there was also a reduction in SBP and DBP of  $-1.3$  (95% CI,  $-2.6$ – $0.0$ ) mmHg ( $P < .05$ ) and  $-0.6$  ( $-1.5$ – $0.2$ ) ( $P = \text{NS}$ ), respectively. A comparison of the low versus the intermediate sodium intakes with the control Western diet indicated a further reduction in SBP of  $-4.6$  ( $-5.9$  to  $-3.2$ ) mmHg ( $P < .01$ ) and  $-2.4$  ( $-3.3$  to  $-1.5$ ) mmHg ( $P < .001$ ). The SBPs and DBPs with the DASH diet were also further reduced with the low as compared to the intermediate sodium intake by  $-1.7$  ( $-3.0$  to  $-0.4$ ) mmHg ( $P < .01$ ) and  $-1.0$  ( $-1.9$  to  $-0.1$ ) mmHg ( $P < .01$ ), respectively [318].

Perhaps most notably, these BP reductions with the DASH low-sodium diet were in addition to the BP-lowering effects of the DASH diet itself. At each level of sodium intake, the SBPs and DBPs were significantly

lower with the DASH diet as compared to the control diet except for the DBP with the low-sodium diet. With the low sodium intake, the mean DBP with the DASH diet was lower than with the Western diet, but not significantly so. The BP-lowering effects of low sodium intakes were greater in the subjects who had the higher BPs than in those who were normotensive; this was observed in the individuals assigned to the control Western diet as well as in those assigned to the DASH diet. A greater reduction in BP was observed in black subjects at intermediate and low levels of sodium intake as compared to white participants [320]. Moreover, the DASH diet with reduced sodium intake lowered BP more effectively in the hypertensive participants who were older than 45 years than those who were 45 years of age or younger [320].

### **What is in the DASH diet that lowers blood pressure?**

The answer to this question is not clear, but the following factors in the diet have been identified as possibly contributing to the lowering of BP.

#### **Nitrate**

Webb and coworkers described a possible role for nitrate in the BP-lowering effects of the DASH diet. This latter diet is high in vegetables [321,322], and vegetables contain substantial amounts of nitrate ( $\text{NO}_3$ ). Ingested nitrate is absorbed from the stomach and small intestine into the circulation, where some nitrate is secreted into saliva and converted to nitrite ( $\text{NO}_2$ ) by the action of bacteria on the tongue. This nitrite is then swallowed where gastric acid converts the nitrite to the vasodilator nitric oxide ( $\text{NO}$ ). In one study, healthy volunteers were randomized to drink either beetroot juice, a rich source of inorganic nitrate, or water in a crossover design. After drinking beetroot juice, plasma nitrate and nitrite rose, and SBP and DBP fell by  $-10.4$  and  $-8.1$  mmHg, respectively [321]. The volunteers not only repeated this activity but also spit out their saliva continuously for several hours so that the nitrite would not be swallowed and thereby exposed to gastric acid. During this time, plasma nitrate again rose, but there was no rise in plasma nitrite, and SBP was significantly higher as compared to when they were allowed to swallow. Ingesting the beetroot juice and swallowing saliva also reduced endothelial dysfunction as indicated by protection against the suppression of the flow-mediated dilation of the brachial artery following ischemia/reperfusion. Finally, swallowing beetroot juice also inhibited the aggregation of platelets that were exposed to ADP or collagen [321].

#### **Dairy products**

A systematic review and metaanalysis reported that ingestion of dairy foods reduces the development of

elevated BP, but this effect has been ascribed to the low-fat dairy foods but not to the high-fat dairy foods [323]. Increased intake of liquid or semiliquid dairy products (e.g., milk or yogurt) but not cheese was associated with the lower incidence of elevated BP. This difference in BP levels might be related to the sodium and potassium content of different dairy products. The higher potassium and lower sodium content of milk and other liquid dairy foods compared with cheese could explain, in part, the lack of association observed between BP and cheese consumption. The US Department of Agriculture states that two slices (1 oz) of cheddar cheese contain 210 mg of sodium, whereas one cup of milk contains 130 mg of sodium [324].

### Other factors

The metabolomic composition of stored sera from the participants of the DASH study has been studied [325]. The serum concentrations of 97 compounds were significantly different in the participants when they were fed the DASH diet as compared to the control Western diet. Among these different serum concentrations, *N*-methylproline, stachdrine, tryptophan betaine, chiro-inositol, methyl glucopyranoside, and  $\beta$ -cryptoxanthin were significantly increased during ingestion of the DASH diet as compared to the control Western diet, and serum theobromine, 7-methylurate, 3-methylxanthine, and 7-methylxanthine were significantly decreased. Future investigations of these compounds may reveal the mechanisms by which the DASH diet lowers BP.

### The Mediterranean diet

This diet is based on the traditional foods eaten by peoples living in countries bordering the Mediterranean Sea and has been epidemiologically associated with reduced cardiovascular disease and mortality [326,327]. The diet is characterized by the daily intake of vegetables, fruits, whole grains and healthy fats, frequent consumption of fish, poultry, beans and eggs, moderate intake of dairy products, and limited intake of red meat. A recent meta-analysis of randomized and nonrandomized controlled trials investigated the effectiveness of the Mediterranean diet on BP as well as other types of diets such as the DASH diet, the low-calorie diet, the low-sodium, or the high potassium diet [328]. Metaanalyses of four trials indicated that the Mediterranean diet significantly reduced DBP (mean difference  $-1.81$  mmHg, 95% CI  $-2.24$ ,  $-1.38$ ), but not SBP (mean difference  $-1.17$  mmHg, 95% CI  $-2.81$ ,  $0.46$ ) [328]. A metaanalysis of cohort and case-control studies that investigated the effectiveness of the Mediterranean diet on clinical outcomes demonstrated that people who had high Mediterranean diet scores (MDS) [186,329] had greater survival [330]. A high MDS indicates that the usual diet is similar to the

Mediterranean diet. Diets like the Mediterranean diet may improve vascular function, as indicated by a greater forearm blood flow in response to a vasodilator challenge [331]. The Mediterranean diet also appears to increase vascular endothelial progenitor cells, which potentially inhibit atherosclerotic lesions in type 2 diabetic patients [332].

The mechanisms by which the Mediterranean diet lowers BP may include the following: as indicated in the DASH study, diets high in fruits and vegetables may reduce BP [317]. The BP-lowering effects of nitrate [27,322] and glutamic acid, which are present in higher amounts in vegetable proteins [211], may contribute. Moreover, the increased amounts of MUFAs and phenolic compounds due to the elevated intake of olive oil with the Mediterranean diet may also contribute to the antihypertensive effects of these high fruits and vegetables diets [333].

### The PREDIMED study

The effectiveness of the Mediterranean diet was investigated in a multicenter trial in Spain, the Prevención con Dieta Mediterránea or the PREDIMED study [334,335]. This study enrolled 7447 participants with ages between 50 and 80 years old who had either type 2 diabetes or three or more major cardiovascular risk factors. The participants were randomly assigned to one of the following dietary intervention groups: a Mediterranean diet supplemented with EVOO; a Mediterranean diet supplemented with nuts; or a control low-fat diet, which was reduced in fat content and offered, each day, three or more servings each of low-fat dairy products, and bread, potatoes, pasta or rice, and two or more servings each day of vegetables. The two Mediterranean diet groups were advised to eat at least three servings per week of fish, especially fatty fish, and seafood; the low-fat diet group was encouraged to eat at least three servings per week of lean fish and seafood. All three diet groups were advised to eat at least three servings per day of fresh fruits and at least two servings per day of vegetables.

The primary endpoint was a composite of myocardial infarction, stroke, or cardiovascular death. The original results, published in 2013, indicated that the Mediterranean diet with either EVOO or nuts was associated with a better primary endpoint [334]. However, protocol deviations related to inconsistent randomization and allocation of participants to the different treatment arms were revealed later, and the original article was retracted [335]. The revised analyses without the assumption of random allocation were published in 2018 [335]. These revised analyses also indicated that the HRs for the primary endpoint were 0.69 (95% CI, 0.53–0.91) for the Mediterranean diet with EVOO and 0.72 (95% CI, 0.54–0.95) for the Mediterranean diet with nuts. These findings seem to

confirm the effectiveness of the Mediterranean diet for the prevention of cardiovascular disease [336]. Several post hoc analyses of the PREDIMED study suggested that the Mediterranean diet decreases both office-measured [337] and 24-hour ambulatory BPs [338]. These antihypertensive effects of the diet may be due to the increase in nitric oxide production from ingestion of dietary nitrates and polyphenols rich in EVOO or nuts [322,339].

### **The PREMIER clinical trial**

The DASH low-sodium diet has also been modified to add a weight loss component and other health-enhancing interventions [320]. In the PREMIER Clinical Trial, 810 participants with prehypertension or stage 1 hypertension, who had SBP of 120–159 mmHg and DBP of 80–95 mmHg, were examined as to whether these individuals can make multiple lifestyle changes that lower BP and reduce their risk factors for cardiovascular disease [106,340]. Subjects, who were mostly overweight or obese, were randomly assigned to one of three treatment groups: (1) one 30-minute counseling session on diet and physical activity, plus educational materials, but no counseling on behavioral changes (i.e., advice only); (2) an intensive behavioral intervention to achieve a set of EST healthy lifestyle goals, including weight loss, dietary sodium reduction to no more than 100 mEq/day, increased physical activity and limited alcohol intake; or (3) the EST intervention with the DASH diet (EST + DASH) [340]. Groups 2 and 3 were scheduled to have 18 counseling sessions over the 6 months of the trial.

The results of the PREMIER Trial indicated that both the EST and the EST + DASH interventions lowered SBP to a similar degree and significantly more than in the advice-only group. After subtracting the BP changes in the advice-only group, the EST and the EST + DASH intervention groups showed significant reductions at 6 months in SBP and DBP of  $-3.7/-1.7$  and  $-4.3/-2.6$  mmHg, respectively. The prevalence of hypertension at 6 months was similar in the two intervention groups and significantly lower than in the advice-only group. However, in the subgroup of patients with the metabolic syndrome, the EST-lowering effect on SBP was not significantly greater than with advice-only, whereas EST + DASH had a similar effect in those with and without this syndrome [341]. Moreover, the EST + DASH regimen after 6 months lowered SBP equally effectively in prehypertension and stage-1 hypertension patients who did or did not have the metabolic syndrome, whereas the EST regimen alone did not lower SBP as effectively in individuals who had the metabolic syndrome [341]. Compliance to the treatment regimens was fairly good, and the EST and EST + DASH interventions also

differed significantly from the advice-only group with regard to greater weight loss, increased physical fitness, and reduced serum total cholesterol and insulin resistance [106,341]; they showed a trend toward lower urine sodium that was significant only in the EST group. Urinary sodium excretion at 6 months averaged  $136.2 \pm \text{SD } 64.6$  and  $145.6 \pm 71.6$  mEq/day with the EST and EST + DASH interventions, respectively.

A randomized controlled trial was conducted in Turkey involving 70 mildly hypertensive overweight or obese men and women, of whom 60 completed the trial [342]. Subjects were counseled repetitively for 3 months to follow lifestyle changes similar to those of the EST + DASH study. The knowledge conveyed in the counseling sessions addressed was the reduction of body weight, sodium intake, and alcohol intake, increased physical exercise, quitting cigarette smoking cessation, and learning stress management. The dietary recommendations were mainly based on the DASH diet. Participants in the control group were provided with routine outpatient services and were asked to maintain their usual lifestyles. Six months after the onset of the study, the interventional group showed improvements in body weight, BP, serum lipids, and lifestyle patterns.

The DASH diet also decreased the prevalence of the metabolic syndrome in other studies [343,344]. The benefits of these dietary and lifestyle interventions have been sufficiently impressive so that they have been incorporated into the recommendations for the prevention and treatment of hypertension by many national advisory groups and are included in the therapeutic lifestyle changes of the Joint National Committee (JNC) [345]. These groups now commonly recommend a DASH low-sodium type of diet along with recommendations similar to the EST lifestyle changes described earlier [345–348].

### **The Nordic diet**

The Nordic diet consists of traditional foods originating from the Nordic countries. The nutrient content of this diet is based on the Nordic Nutrition Recommendations 2004 [349], which was also influenced by such other diets as the Mediterranean, Portfolio, DASH, and the NCEP diets. The Nordic diet is rich in fruits, berries, vegetables, legumes, low-fat dairy products, and fatty fishes that are readily obtained in Nordic countries [350]. Several clinical trials confirm the BP-lowering effects of the Nordic diet. The NORDIET trial compared the changes in BP and the lipid profiles between participants randomized to the Nordic diet and the usual Western diet. At the end of the 6 weeks of study, the SBP decreased significantly in the Nordic diet group by  $-6.55 \pm \text{SD } 13.18$  mmHg compared to the change in SBP with the control Western

diet ( $+0.60 \pm 11.25$  mmHg); difference between the Nordic and Western diets ( $P = .008$ ) [350]. Another randomized study, SYSDIET, also found that after 12 weeks of intervention, ambulatory BP measurements were significantly lower in the Nordic diet group than in the control diet group, which was the isoenergetic diet with the average nutrient intake in the Nordic countries [351].

### ***Effect of dietary sources of fuel on blood pressure***

Since the DASH diet provides less fat and more protein than a typical Western diet, is it possible that these differences in fuel sources could contribute to its BP-lowering effects? As indicated earlier, amino acids and peptides derived from ingested proteins may have BP-lowering effects [204–206,209,210,213,214]. The OmniHeart study examined the relative contribution of diets providing relatively high amounts of carbohydrates, proteins, or MUFA to BP changes [8,317]. Adults with prehypertension or untreated stage 1 hypertension were randomly assigned to receive each of these three types of diets in a crossover design. The high-protein diet increased protein intake to 25% of total energy intake, and the high monounsaturated diet increased fat to 37% of total energy intake. The carbohydrate content in these latter two diets was 48% of total calories, as compared to 58% of total calories with the high-carbohydrate diet which is similar to the composition of the DASH diet. Weight was kept stable by adjusting total energy intake. The higher protein diet and the higher monounsaturated fat diet were each more effective at lowering BP as compared to the high-carbohydrate diet. Whether this was due to the lower carbohydrate intake or the higher protein or fat intake is not clear. However, these findings are consistent with observational studies indicating that higher intakes of vegetable protein or polyunsaturated fat are associated with a lower death rate from coronary heart disease and greater survival [352,353].

A metaanalysis of 10 studies comparing the effects of high carbohydrate versus high *cis*-monounsaturated fat diets also indicated that the high-carbohydrate diets were associated with slightly, but significantly higher SBP [mean difference, 2.6 mmHg (95% CI, 0.4–4.7)] and DBP [mean difference, 1.8 mmHg (95% CI, 0.01–3.6)] [354]. The same trends were noted when the analysis was restricted to six randomized crossover studies, but the results were no longer statistically significant. As indicated earlier, intake of sugar-sweetened beverages and, in people who had high urinary sodium, the amount of fructose and glucose intake was directly correlated with SBP and DBP [54,56]. It is pertinent that higher protein diets have also been associated, short-term, with improved serum lipid levels and possibly reduced insulin resistance

and other metabolic benefits in patients with type 2 diabetes mellitus [355]. Recent metaanalyses, however, have not demonstrated a beneficial effect of high-protein diets on serum glucose, insulin, or HbA1c levels [355,356]. It is not yet clear whether these higher protein diets are safe or efficacious for long-term use, at least in people with limited nitrogen tolerance, such as those with CKD or liver failure [357]. They may be contraindicated in people with early CKD, as they are in persons with more advanced CKD, because of the potential risk of accelerating progressive kidney failure and also, in the latter condition, by engendering uremic toxicity. They may also be hazardous to people with liver failure and/or with genetic metabolic disorders involving the biochemical processing of urea, ammonia and the amino acids involved in their synthesis. More research into these questions would be helpful.

The amount of energy intake per se can influence the effects of sodium on BP. A post hoc analysis of the DASH study revealed that the relationship between increased sodium intake and higher BP was steeper for the participants with lower energy intakes [358]. Some authors have suggested that the recommendations for dietary sodium intake might be based on the amount of energy intake as well as the absolute amount of sodium ingested [358].

### **Long-term adherence and blood pressure responses to health-enhancing lifestyles**

#### ***Longer term experience with the previously described clinical trials***

The long-term responses to healthy diet recommendations are being examined in many studies. As indicated earlier, the HPT and Trials of Hypertension Prevention (TOHP Phase I and Phase II), in which patients were counseled on weight-reduction and/or sodium-reduction diets for up to 4 years, indicated that there was a progressive loss of adherence to these dietary intakes [310,314–316]. TOHP Phase I also indicated a reduced OR of developing hypertension 7 years after the onset of the trial, in the people in the weight reduction group (OR 0.23; 95% CI, 0.07, 0.76;  $P = .02$ ) [359]. The incidence of hypertension tended to be lower in the sodium reduction group but this difference was not significant (OR 0.65; 95% CI, 0.25, 1.69;  $P = .37$ ) [359]. The HPT and TOHP Phase II trials also demonstrated that some antihypertensive effects remained 3 or 4 years after the onset of the trial [310,314–316].

In the PREMIER Clinical Trial, participants, who were originally followed for 6 months, were then monitored for an additional 12 months during which the

advice-only group underwent one additional 30-minute counseling session and received educational materials; the EST intervention and EST intervention + DASH diet groups attended monthly group sessions and three individual counseling sessions and were asked to keep food diaries, monitor their dietary energy and sodium intake, and record the minutes of physical activity. At 18 months after the onset of the PREMIER Trial, the EST intervention and EST intervention + DASH diet groups, in comparison to the advice-only group, each showed greater weight losses of  $-2.2$  and  $-2.7$  kg, respectively ( $P < .01$  for each group), and significantly lower energy intakes [360]. Precisely 25% of both EST intervention groups attained the target weight loss goal of  $-6.8$  kg. Urinary sodium excretion was also significantly lower in both intervention groups as compared to the advice-only group, by  $-16.7$ -mmol sodium and  $-15.4$ -mmol sodium, respectively. Compared to the advice-only group, the OR for hypertension was 0.83 and 0.77, respectively, in the EST and EST + DASH groups at 18 months and was significantly lower only in the EST + DASH group. Among people who were hypertensive at baseline, the OR for remaining hypertensive was significantly lower in both intervention groups as compared to the advice-only group. However, the change in BP levels at 18 months was not different among the three groups. This might be due to the reduction of antihypertensive medications. The ORs of being on antihypertensive medications compared to the advice-only group were 0.57 (95% CI 0.41, 0.81) and 0.62 (95% CI 0.45, 0.85) in the EST and EST + DASH diet groups, respectively, at the end of 18 months.

#### **Other longer term studies on diet, adherence, and blood pressure**

Folsom et al. employed a DASH diet index score to evaluate the long-term consequences in nonhypertensive participants in the Iowa Women's Health Study who ingested diets with food patterns similar to the DASH diet [361]. Adjusting for age and energy intake, they found that greater adherence to a DASH-type diet was associated with a lower incidence of hypertension and cardiovascular mortality, but these associations were not statistically significant after adjustment for other risk factors. However, these women were assessed while they ingested their usual intakes, and they did not undergo specific training and follow-up with regard to adherence to the DASH diet.

The WHI Dietary Modification Trial evaluated the effect of intensive behavioral modification to ingest a diet of increased fruits, vegetables, and whole grains and reduced fat on BP and other clinical outcomes, including cardiovascular events [362]. A total of 48,835 postmenopausal women were randomized to this treatment or to receive dietary educational materials.

They were followed for a mean of 8.1 years. The primary aim of this study was to assess reduction in the incidence of breast and colorectal cancers. The diet was not specifically designed to lower sodium or energy intake, although there was a small decrease in energy intake and body weight in the treatment versus the control group. Although the intake of all dietary components changed in the prescribed direction, SBP did not change significantly, and there was a significant but very modest ( $-0.31$  mmHg) reduction in DBP. Moreover, there was no reduction in the incidence of coronary heart disease, stroke, or all cardiovascular events with this diet.

The DEW-IT study was a 9-week intensive healthy lifestyle modification intervention that evaluated a low-energy version of the DASH diet and a nonactive interventional arm in 44 overweight and obese hypertensive patients [363]. There was significantly greater weight loss with the lifestyle intervention at the end of the 2-month period. However, at 1 year of follow-up, the weight loss group had regained almost all of their lost weight, and their weight change was not different from the nonintervention group [364].

The ADAPT study evaluated changes in lifestyle and clinical characteristics in 241 overweight or obese hypertensive adults after they were randomized to UC or an intensive program of lifestyle counseling [365,366]. At 4 months into the study, which was at the end of the 4-month interventional period, and at 16 months, which was the end of the 12-month period of follow-up, there was significantly greater weight loss associated with a more healthy dietary intake in the lifestyle changes group. Ambulatory BP was lower at 4 months after starting counseling but not after the 1-year follow-up [365]. Three years after completion of the first 4-month intervention period in the original study, that is, after an additional 2 years of follow-up, the relative improvements in the lifestyle group, as compared to UC, were limited to increased physical activity, some food intakes, and a minor decrease in serum cholesterol, but no difference in weight loss, BP, changes in antihypertensive medications, or other risk factors [367].

Other lifestyle modification programs also report that initial weight losses are not maintained long term [368]. However, Viera et al. evaluated adults who had participated in a survey and who indicated that they had been told they were hypertensive [369]. Those adults who also stated that they were advised on lifestyle changes were significantly more likely to describe healthy changes in lifestyle (e.g., changed eating habits, including reduced salt and alcohol intake or exercise) than those who did not recall being advised on lifestyle changes. It is emphasized that these data were obtained from participant reports.

### **Remote counseling using communications technology**

More recent studies investigated the effectiveness of promoting participant adherence with the use of information and communications technology. The TEXT ME study was a single-blind, randomized clinical trial that included 710 patients with proven coronary heart disease [370]. The intervention group received four text messages regarding healthy lifestyle habits, including at least one message per week focusing on diet, in addition to standard care, whereas the control group received standard care. The outcome of this study was adherence to eight Australian dietary guidelines, that is, consumption of vegetables, fruits, oils, spreads, fish, takeaway food, salt, and standard alcohol drinks. The participants received four text messages per week over a period of 6 months with at least one per week focusing on diet. The proportion of the participants who adhered to four or more dietary recommendations was significantly higher (93%) in the text message group than in the control group (75%, relative risk, 1.23, 95% CI, 1.15–1.31,  $P < .001$ ) [370].

Another randomized controlled study investigated the effectiveness of short message systems regarding healthy diet, medication, and smoking cessation on adherence to these measures [371]. Adherence was assessed by the Mediterranean Diet Adherence Screener, Medication Adherence Scale, and Readiness to Quit Ladder. The participants demonstrated a higher adherence to the Mediterranean diet ( $P < .001$ ) and medication ( $P = .001$ ), whereas no difference was found in terms of smoking. It should be noted that these last two studies had short observational periods, that is, 6 [370] and 3 months [371], respectively. The effectiveness of these interventions over longer periods of time needs to be investigated.

Friedberg et al. conducted a randomized prospective controlled trial of 533 adults who had repeated BP measurements over 6 or more months indicating poorly controlled BP despite being prescribed antihypertensive drugs [372]. These investigators evaluated the effectiveness on BP control of either stage-matched intervention (SMI) or nontailored health education intervention (HEI) as compared to UC treatment. Patients in SMI received tailored monthly phone counseling for exercise, diet, and medications based on their current stage of change which was assessed by asking them a set of validated stage-of-change questions. The HEI group received nontailored monthly telephone counseling of standard information concerning hypertension, diet, medication, and exercise. After 6 months, BP control (defined as BP  $< 130/80$  mmHg for diabetic or CKD patients, BP  $< 140/90$  mmHg for other patients) was attained in 64.6% of the SMI

participants ( $P = .001$  vs UC group), 54.3% of the HEI patients ( $P = .108$  vs UC), and 45.8% of the UC group. Moreover, changes from baseline in the DASH diet score were only significant in the SMI group ( $P = .013$ ), but not in the HEI group ( $P = .318$ ), as compared to the UC group [372]. These findings reinforce the importance of individualizing the approach to each patient to maximize adherence to healthy lifestyles, including healthy diets, and to control BP.

### **Challenges to diet and lifestyle approaches for preventing and treating hypertension**

Other researchers report rather mediocre long-term (i.e., more than 6–24 months) adherence to these foregoing dietary regimens. Adherence to diet prescription and weight loss, although often statistically significantly better than baseline or than the control diets, were often small [360,373]. For example, many obese patients have 15, 25, or more kg of excess body fat. Dietary weight reduction programs are often considered rather successful if the participant loses 5 or 6 kg over the long term. It is possible, of course, that a disproportionately healthy benefit may be obtained with these rather modest fat losses by obese patients.

This dilemma may be more problematic serious for some ethnic groups that, studies indicate, may have greater difficulty adhering to some components of the DASH diet [374,375]. Examination of the NHANES data for the years 1999–2004 indicates that only  $19.4 \pm 1.2$  (SEM)% of 4386 people with known hypertension had a diet similar to the DASH diet [376]. These values are substantially lower than the proportion of known hypertensives who were accordant with the DASH diet ( $26.7\% \pm 1.1\%$ ) in the NHANES data for 1988–94 [376]. Indeed, the NHANES data indicate that adherence to healthy lifestyles appears to be diminishing in the United States [377]. Although at least most of the NHANES participants probably had not been trained in the importance of or the preparation of the DASH diet, the principles of the DASH diet have been recommended in guidelines promoted by the JNC on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure and other health and health-care organizations for many years [3,378–380]. Large numbers of Americans are now counseled in healthy lifestyle modifications, although some population groups are less commonly counseled, particularly the young, perhaps the less educated, and people with low cardiovascular risk factors [341].

Thus the results concerning adherence to the DASH or other dietary prescriptions to reduce BP or cardiovascular events are somewhat conflicting. As pointed out by Logan [381], there are several possible explanations

for the differences in adherence to these diets. The DASH trial was short-term, and all food was prepared in research kitchens and provided to the subjects at no cost. Moreover, on weekdays either lunch or supper meals were eaten in a research unit [317,382]. In contrast, in other studies, the food had to be purchased and prepared by the participants. When food must be purchased and prepared for long or indefinite periods of time by the consumer who is not participating in an intensively controlled research protocol, adherence may fall. Another question concerns the cost-effectiveness of long-term counseling to maintain adherence to healthy lifestyles and diets. In some centers, counseling has been done by health-care workers who are more expensive. People who are not such professional health-care workers, as dietitians or nurses, can be trained rather quickly to become effective lifestyle coaches [383].

Long-term remote counseling for weight reduction by telephone, a program-specific web site, and email was examined as a strategy for effectively promoting weight reduction at greater efficiency and less cost (please also refer to the “Remote counseling using communications technology” section) [384]. Primary care providers played a supportive role in the program but were not directly involved in the interventions. In this latter trial, one group of obese participants received exclusively remote but frequent counseling; another group received a combination of incenter person-to-person counseling plus three remote counseling sessions [384]. A third group served as controls. At 24 months, weight loss averaged  $-0.8$  kg in the control group,  $-4.6$  kg in the group receiving remote counseling ( $P < .001$  vs controls), and  $-5.1$  kg in the group receiving direct person plus remote counseling ( $P < .001$  vs controls). Thus a combination of employing trained laypeople as counselors plus the use of remote counseling may substantially reduce the costs of diet and lifestyle-induced weight loss programs, especially if the techniques for weight reduction can be made more effective.

The use of bariatric surgery to control obesity and its adverse consequences may be an important adjunct to dietary measures to control hypertension and reduce cardiovascular risk (see Chapter 40: Nutritional and Metabolic Management of Obesity and The Metabolic Syndrome in Patients with Chronic Kidney Disease and Chapter 41: Bariatric Surgery and Kidney Disease). The long-term, multiyear benefits to people who adhere closely to the DASH or DASH low-sodium diets also are not yet known, although it seems reasonable to believe that these diets and lifestyle changes will be healthy indefinitely [385]. Moreover, it is not entirely clear that these diets are similarly effective for all racial, ethnic, and age groups and whether there are certain morbid conditions for which these

diets may not be beneficial. In both DASH studies, the potassium content of the control diet was below the 25th percentile of the estimated usual potassium intake in the United States [381]. Moreover, most of the DASH study patients were African-American [317], a population whose BP is particularly potassium-sensitive and who may require a high potassium intake in the range of the DASH diet to avoid sodium sensitivity induced by potassium deficiency [145]. Thus these results may not be as applicable to non-African-Americans or to people who are already ingesting higher potassium diets. On the other hand, the large-scale, observational, multiyear Nurses’ Health Study II indicated that those individuals who followed a low-risk diet and low-risk lifestyle had a lower self-reported incidence of hypertension [386]. It is relevant and encouraging that the demonstrated BP-lowering effects of healthy dietary regimens and lifestyles coupled with difficulty in adherence has provided a commercial incentive to develop functional foods and nutraceuticals that may provide recommended nutrients [387]. Hopefully, these products will enhance the ability of people to follow the recommended dietary guidelines.

### Exercise

Exercise training and its physiological, metabolic, and clinical consequences are discussed in Chapter 51: Exercise Training for Individuals With Advanced Chronic Kidney Disease. Some but not all studies of exercise and BP suggest that regular exercise training may reduce BP. Aerobic exercise training and resistance training are reported to decrease BP in prehypertensive and stage 1 hypertensive individuals and may lower serum cholesterol, particularly when combined with a low-fat intake [388]. Exercise may also accelerate weight reduction in obese individuals who are ingesting a low-calorie diet [389]. A cohort of 3148 healthy adults underwent studies of cardiorespiratory fitness, determined by treadmill exercise, which was measured over a 6-year interval of time [21]. Improvement in cardiorespiratory fitness was associated with a reduction in the incidence of hypertension, the metabolic syndrome, and hypercholesterolemia. A gain in the percent body fat or BMI was each associated with an increased incidence of hypertension, metabolic syndrome, and hypercholesterolemia [21].

The Exercise and Nutrition interventions for Cardiovascular Health study investigated the combined effects of the DASH diet and exercise to reduce body weight [390]. The study randomly assigned 144 patients with SBP of 130–159 mmHg or DBP of 85–99 mmHg to the original DASH diet alone (DASH-A), the DASH diet combined with a behavioral weight management program that included a supervised aerobic exercise training program three times per week for 30 minutes per session

(DASH-WM), and the usual diet control (UC) in which the participants maintained their usual dietary and exercise habits. After a 4-month period of intervention, the clinic-measured BP levels, ambulatory BP levels, and body weights were significantly lower in the DASH-WM group as compared to the DASH-A and UC groups [390]. The results of this study further support a significant role for exercise and body weight reduction for lowering BP.

Two mechanisms by which regular physical exercise may lower BP include a reduction in oxidative stress and amelioration of insulin resistance and its consequent hyperinsulinemia [391]. In the presence of oxidative stress, 8-Iso-PGF $2\alpha$ , a potent vasoconstrictor, is produced [391]. Insulin resistance with hyperinsulinemia impairs NO synthesis, which will predispose to hypertension.

It is important to remember that the transient increase in BP that occurs when normal people exercise may be greatly exaggerated in hypertensive individuals. Thus BP should be monitored carefully in hypertensive persons who are embarking on exercise training, until it is ascertained that dangerous increases in BP do not occur [392].

### **Anorexigenic medicines**

Many anorexigenic medicines have been evaluated for their effects on promoting fat loss in overweight or obese people. Studies indicate that a reduction in BP may accompany weight loss [301,393,394]. Most of these drugs have been abandoned because of adverse side effects. One anorexigenic agent still in use is orlistat, a lipase inhibitor that reduces intestinal fat absorption. Orlistat induces weight loss more effectively than placebo treatment, on average by roughly 4 kg (mean difference  $-3.73$ ; 95% CI,  $-4.65$ ,  $-2.80$ ) [394]. Orlistat may cause disturbing gastrointestinal symptoms of flatulence, bloating, abdominal pain, and diarrhea [393]. Treatment with orlistat also lowers BP [301,395]. In a metaanalysis, there was a statistically significant reduction in SBP and DBP with orlistat of  $-2.5$  and  $-1.9$  mmHg, respectively [395].

Phentermine–topiramate and naltrexone–bupropion are two other medications that are prescribed for body weight reduction in patients with morbid obesity. Phentermine is a central norepinephrine-releasing drug, which was approved in 1959 and remains a popular anti-obesity drug in the United States. Topiramate has several pharmacological mechanisms of action and is prescribed for epilepsy and migraine prophylaxis. However, Topiramate has dose-dependent neuropsychiatric adverse events, including memory impairment and mood alterations, including depression, which impeded its use as monotherapy for obesity [396].

The combination of these two drugs was tested for the treatment of obesity and hypertension. A 56-week phase 3 trial recruited 2487 patients with BMI of  $27\text{--}45$  kg/m $^2$  and two or more of the following comorbidities: hypertension, dyslipidemia, diabetes or prediabetes, or abdominal obesity. Patients were randomly assigned to receive a placebo, once-daily phentermine, 7.5 mg, plus topiramate, 46.0 mg, or once-daily phentermine, 15.0 mg, plus topiramate, 92.0 mg, in a 2:1:2 ratio [396]. At 56 weeks the change in body weight was  $-1.2\%$  (95% CI,  $-1.8$ ,  $-0.7$ ),  $-7.8\%$  (95% CI,  $-8.5$ ,  $-7.1$ ,  $P < .0001$ ), and  $-9.8\%$  (95% CI,  $-10.4$ ,  $-9.3$ ;  $P < .0001$ ) in the patients assigned to placebo, once-daily phentermine 7.5 mg plus topiramate 46.0 mg, or once-daily phentermine 15.0 mg plus topiramate 92.0 mg, respectively.

The group assigned to phentermine–topiramate experienced significant decreases in SBP and DBP. Changes in SBP from baseline to week 56 were  $-2.4$  mmHg (95% CI,  $-3.3$ ,  $-1.5$ ),  $-4.7$  mmHg (95% CI,  $-5.9$ ,  $-3.5$ ;  $P = .0008$ ), and  $-5.6$  mmHg (95% CI,  $-6.5$ ,  $-4.6$ ;  $P < .0001$ ) in the patients assigned to placebo, once-daily phentermine 7.5 mg plus topiramate 46.0 mg, or once-daily phentermine 15.0 mg plus topiramate 92.0 mg, respectively. Changes in DBP from baseline to week 56 were  $-2.7$  mmHg (95% CI,  $-3.3$ ,  $-2.1$ ),  $-3.4$  mmHg (95% CI,  $-4.2$ ,  $-2.6$ ;  $P = .1281$ ), and  $-3.8$  mmHg (95% CI,  $-4.4$ ,  $-3.2$ ;  $P = .031$ ) in the patients assigned to placebo, once-daily phentermine 7.5 mg plus topiramate 46.0 mg, or once-daily phentermine 15.0 mg plus topiramate 92.0 mg, respectively. Common adverse events with this drug combination were dry mouth, paresthesia, constipation, insomnia, dizziness, and dysgeusia. Due to adverse events, 89, 58, and 192 participants, respectively, discontinued their assigned intervention out of 994, 498, and 995 persons assigned to placebo, phentermine 7.5 mg plus topiramate 46.0 mg, and phentermine 15.0 mg plus topiramate 92.0 mg, respectively.

Combined treatment with sustained-release naltrexone and bupropion was developed to stimulate the hypothalamic proopiomelanocortin neurons with bupropion while simultaneously blocking opioid-mediated proopiomelanocortin autoinhibition with naltrexone. Naltrexone and bupropion are prescribed for addictive disorders. These drugs synergistically modulate the mesolimbic reward pathways and reduce food intake. A 56-week study was conducted in 1742 participants who had a BMI of  $30\text{--}45$  kg/m $^2$  with uncomplicated obesity or a BMI of  $27\text{--}45$  kg/m $^2$  and controlled hypertension and/or dyslipidemia [397]. Study subjects were randomly assigned in a 1:1:1 ratio to receive sustained-release naltrexone, 32 mg/day plus sustained-release bupropion 360 mg/day combined in fixed-dose tablets (NB32), sustained-release naltrexone 16 mg/day plus sustained-release bupropion 360 mg/day combined in fixed-dose tablets (NB16), or

placebo twice a day. Naltrexone–bupropion at both doses was associated with a significantly reduced body weight at the end of the 56-week period, but neither dose of these medicines had a significant effect on SBP or DBP [397].

## Conclusion and recommendations

Many studies indicate that nutritional intake and nutritional status have a major effect on the probability of developing hypertension and on the severity of hypertension in the general population. Appropriate dietary management may prevent the onset of hypertension and eradicate or improve mild hypertension in many people. Diets can be a useful adjunct to pharmacological therapy for the treatment of more severe, EST hypertension. Key nutritional elements that prevent or ameliorate hypertension include the prevention or treatment of obesity, the low-sodium DASH diet, adequate potassium intake, and possibly sufficient intake of fish oil, magnesium, and certain types of tea. Dietary intake or avoidance of certain other nutrients may also affect the incidence or severity of hypertension. Some evidence indicates that regular exercise may reduce resting BP; exercise, of course, has other health-enhancing advantages. A dietary approach to either prevent or treat hypertension is indicated in Table 37.5. For patients who have a major elevation in BP, it is very uncommon for their hypertension to respond adequately to dietary management alone. These individuals will almost certainly also require medicines to control their hypertension, but dietary control may still improve the ease with which their elevated BP may be managed.

**TABLE 37.5** A suggested dietary approach to prevent or treat hypertension<sup>a,b</sup> [399].

1. Maintain desirable body weight
2. Use the DASH diet (a diet high in fruits, vegetables, and low-fat dairy products and low in saturated and total fat)
3. Limit daily NaCl consumption to 5.85 g/day (2.30 g of sodium/day) or lower
4. Maintain adequate potassium and magnesium intake
5. Recommended calcium intake for noncalcium stone formers (about 1000 mg/day for persons aged 19–50 years and 1200 mg/day for persons ≥ 50 years)
6. For individuals who drink alcohol, no more than two drinks (3–4 units<sup>c</sup>)/day
7. Consider a high omega-3 fatty acid diet (i.e., about 3–6 g/day of fish oil/day)

<sup>a</sup>For persons with a chronic illness, each of these recommendations should be reviewed with his/her physician to ensure that it is compatible with their medical management.

<sup>b</sup>Regular (approximately daily) exercise activity is also recommended.

<sup>c</sup>One unit contains 10 mL or 8 g of pure alcohol. This measure is used in the United Kingdom.

DASH, Dietary approaches to stop hypertension.

Individuals who are obese or have other dietary habits that may predispose to hypertension (e.g., high sodium chloride intake) should be encouraged to inaugurate appropriate dietary therapy. If the BP is substantially elevated, a reasonable approach would be to start pharmacological antihypertensive therapy concomitantly with dietary management. If the patient is committed to dietary therapy of hypertension, he or she may do the following. Once the BP has stabilized at the target level, attempts may be made to gradually withdraw the antihypertensive medicines while maintaining strict dietary management. Exercise training should be encouraged, but only after careful medical evaluation of cardiovascular and hemodynamic activity, including any excessive rise in BP in response to exercise of persons who have hypertension, who are older, or who have major underlying illnesses, such as heart disease or kidney disease.

Ultimately, the most effective behavioral approach to prevent or ameliorate hypertension is by the development of a healthy lifestyle that includes a DASH, low sodium–type diet or Mediterranean-type diet, regular physical exercise, and intake and avoidance, respectively, of those nutrients that appear to lower or increase BP (see Table 37.2).

## Key points

1. Obesity is one of the main nutritional predisposing factors to hypertension.
2. The many mechanisms by which obesity and excessive energy intake predispose to hypertension include increased activity of the renin–angiotensin–aldosterone system, probably a rise in nonaldosterone-mediated mineral corticoid activity, increased sympathetic nervous system activity, insulin resistance, salt-sensitive hypertension, excess salt intake, and the reduced kidney function which is often present in obese individuals.
3. High sodium chloride intake is the other main nutritional predisposing factor to hypertension.
4. Increasing potassium intake, particularly in people with potassium-deficient intakes, may lower BP and reduce the risk of hypertension.
5. Higher intakes of polyunsaturated fatty acids, protein, and possibly certain amino acids, vitamin D, and green coffee bean extract may lower blood pressure (BP).
6. Some evidence suggests that dark chocolate, but not white chocolate, and oolong, green, black, and sour tea may reduce the risk of hypertension. Evidence suggests that excessive energy intake,

sugar-sweetened beverages, fructose, and glucose may raise BP.

7. Large alcohol intakes may increase the risk of hypertension and acutely and chronically raise BP. Some evidence indicates that consumption of low-to-moderate amounts of alcohol may raise BP in African-American men but not in white men or women or African-American women.
8. Certain diets and lifestyle changes, including regular exercise, appear to lower BP in people with prehypertension or mild hypertension and prevent the development of hypertension.
9. The dietary approaches to stop hypertension low-sodium diet, which is high in fruits and vegetables, low-fat dairy products, potassium, magnesium, calcium, and fiber, and low in saturated fatty acids, total fat, and sodium, is such a diet.
10. Long-term adherence to healthy, BP-lowering diets is difficult for many people to attain, and methods for obtaining long-term adherence to such diets and healthy lifestyles continue to be investigated.
11. Bariatric surgical procedures in association with counseling for healthy lifestyle changes appear at present to be the most effective and reliable methods for long-term, major reductions in body fat.

# Nutrition and anemia in chronic kidney disease

*Angela Yee-Moon Wang*

Department of Medicine, Queen Mary Hospital, The University of Hong Kong, Hong Kong, P.R. China

## Prevalence and importance of anemia in chronic kidney disease

Anemia is a frequent complication in chronic kidney disease (CKD) and reflects the severity of CKD. Data from the National Health and Nutrition Examination Survey 2007–10 estimated that 14.0% of the US population had CKD. Anemia, defined as hemoglobin (Hb) levels  $\leq 12$  g/dL in women and  $\leq 13$  g/dL in men, was twice as prevalent in people with CKD (15.4%) as in the general population (7.6%). Furthermore, the prevalence of anemia increased with increasing CKD severity, from 8.4% at stage 1 to 53.4% at stage 5 [1]. In a more recent retrospective analysis based on the United States (US) Veterans Administration, of nearly a million US adult with CKD, 20.6% had anemia and 30% had absolute iron deficiency and 19% had functional iron deficiency [2]. Very high ( $\geq 17$  g/dL) or reduced ( $< 13$  g/dL) Hb levels and CKD were independently predictive of substantially increased risks of death and hospitalization for heart failure [3].

## Causes of anemia in CKD

Many factors contribute to anemia in CKD, a major cause of which is reduction in erythropoietin (EPO) production by the failing kidneys. Iron deficiency, worsening uremia, inflammation, loss of residual kidney function, nutritional deficiencies of folate or vitamin B12, and severe hyperparathyroidism are other important factors for anemia in CKD.

## Mechanisms of anemia and hypoxia-inducible factor pathway in CKD

EPO is predominantly produced by the kidneys and acts on erythroid cells expressing EPO receptors,

controlling their proliferation, differentiation, and survival [4]. Fibroblasts in the renal cortex and outer medulla are the principal cells that produce erythropoietin in response to hypoxia or anemia [5]. The EPO gene is regulated by hypoxia through the hypoxia-inducible factor (HIF) system discovered in 1992 and is a family of heterodimeric transcription factors, including HIF-1 $\alpha$ , HIF-2 $\alpha$ , and HIF-3 $\alpha$  subunits that are oxygen dependent and the HIF-1 $\beta$  and HIF-2 $\beta$  subunits that are constitutively expressed. In normal oxygen conditions, HIF-1 $\alpha$  subunits are hydrolyzed in specific proline residues by prolyl-4-hydroxylase domain (PHD), becoming a target for ubiquitination by von Hippel–Lindau tumor suppressor protein and thus subjected to proteosomal degradation. Under hypoxic conditions, as PHD proteins that require oxygen for hydroxylation of HIF-1 $\alpha$  subunits are inhibited, HIF-1 $\alpha$  is not degraded to the same extent. The stabilized HIF-1 $\alpha$  subunits translocate into the nucleus and heterodimerize with HIF-1 $\beta$  subunits, thus activating hypoxia response genes that encode for synthesis of EPO, EPO receptor, transferrin receptors, vascular endothelial growth factor (VEGF), and glycolytic enzymes, stimulating erythropoiesis, iron availability, and angiogenesis [6].

The kidneys respond to hypoxia or anemia by increasing the number of renal erythropoietin-producing cells (REPCs) that are sensitive to changes in oxygen tension, thus increases EPO production. In face of renal injury or proinflammatory stimuli, the REPCs transdifferentiate into myofibroblasts that lead to extracellular matrix accumulation, collagen production, and renal fibrosis and impair EPO production [7]. Activation of HIFs selectively by genetically inactivating HIF prolyl hydroxylases (PHD1, PHD2, and PHD3) in REPCs would reactivate EPO production in myofibroblast-transdifferentiated REPCs. Notably, combined deletions of PHD1 and PHD3 genes prevented loss of EPO production without causing polycythemia. Loss of PHD2 restored EPO gene expression in injured kidneys but caused polycythemia.

Thus activation of HIF signaling by reactivating EPO production in MT-REPCs is an attractive therapeutic strategy for treating renal anemia [7]. In vivo knockout studies showed that HIF-2 $\alpha$  but not HIF-1 $\alpha$  is the primary regulator of hypoxic EPO induction in both the kidneys and the liver. Mutations that activate HIF-2 $\alpha$  can result in erythrocytosis. Further evidence from cell culture studies suggest that PHD2 serves as the critical oxygen sensor that regulated HIF-2 $\alpha$  upstream stimulation of EPO [8]. However, the role of oxygen sensor PHDs differs between both organs in EPO production. REPCs predominantly use PHD2 and liver cells use all three PHD isoforms equally for degrading HIF-2 $\alpha$  while hepatocytes use all three PHD isoforms equally for degrading HIF-2 $\alpha$ .

### Iron homeostasis

Dietary ferric iron is first reduced to ferrous iron by duodenal cytochrome B (DCytoB). Ferrous iron is

transported into enterocytes lining the gut via divalent metal transporter 1 (DMT1). Transport of ferrous iron out of enterocytes into bloodstream occurs via the iron transporter ferroportin. Once in the bloodstream, ferrous iron is oxidized to ferric iron by ceruloplasmin and is bound to transferrin for transport. Transferrin binds to cellular membrane transferrin receptor 1 (TFR1) and iron is internalized by endocytosis. The utilization of iron is opposed by hepatic peptide hormone hepcidin that is a key regulator of iron availability (Fig. 38.1). Hepcidin is a peptide discovered in the 21st century with a molecular size of 2.7 kD. It is not strongly bound to plasma proteins and is rapidly cleared by the normal kidneys where it is largely reabsorbed and degraded by the proximal tubules. A small proportion of hepcidin escapes this mechanism and can be detected in urine [9], where daily excretion is approximately proportional to serum hepcidin concentrations [10]. Hepcidin is a “hypoferremia”-inducing hormone. It reduces dietary iron absorption from the intestine and blocks release of stored iron both from the macrophages and from the liver by inhibiting

**FIGURE 38.1** Iron metabolism and hypoxia-inducible factor prolyl hydroxylase domain transcription pathway in response to hypoxia or anemia. Under hypoxic conditions the HIF prolyl-4-hydroxylase domain does not inactivate HIF- $\alpha$  that translocates into the nucleus and after dimerization with HIF- $\beta$  activates transcription of EPO in the kidney and in the liver, which stimulates erythropoiesis in the bone marrow. HIF synchronizes EPO production with iron metabolism by stimulating duodenal cytochrome B reductase 1, which reduces Fe<sup>3+</sup> to Fe<sup>2+</sup> and divalent metal transporter 1, which allows iron transport into the enterocyte. Iron is then released into the circulation via FPN, which is also HIF inducible. In the circulation, iron is transported in a complex with transferrin to the reticuloendothelial system in the liver and in the spleen to be stored in the ferritin and to the bone marrow for erythropoiesis. Transferrin also is HIF regulated. Increased erythropoiesis in the bone marrow produces erythroferrone, which suppresses hepcidin in hepatocytes. Hepcidin suppression increases FPN expression on enterocytes, hepatocytes, and macrophages, resulting in increased iron absorption and mobilization from internal stores. EPO, Erythropoietin; FPN, ferroportin; HIF, hypoxia-inducible factor. Reprinted with permission from Locatelli F, Del Vecchio L, De Nicola L, Minutolo R. Are all erythropoiesis-stimulating agents created equal? *Nephrol Dial Transplant* 2020. Mar 24;gfaa034. doi: 10.1093/ndt/gfaa034. Online ahead of print. Ref 65 in this paper.

ferroportin [11]. It thus reduces the availability of stored iron, makes anemia worse, and could contribute to erythropoiesis resistance or restriction. In situation of infection and inflammation, hepcidin levels are upregulated by proinflammatory cytokines, interleukin-6, its receptor, and JAK2-Stat 3 pathway, causing hypoferremia and worsening anemia [12]. This response has a host defense function for siderophilic bacteria of which the pathogenicity is enhanced by iron. Conversely, hypoxia and erythropoiesis stimulator such as erythropoietin-stimulating agent (ESA) negatively regulate hepcidin production and downregulation of hepcidin allows enhanced iron mobilization from the body stores and availability for erythropoiesis (Table 38.1).

### HIF pathway and iron homeostasis

The HIF pathway also regulates iron homeostasis to meet the iron demands of erythropoiesis via direct and

indirect mechanisms. HIF modulates iron handling by upregulating transferrin, TFR1, and ceruloplasmin, allowing greater transport of iron to tissues and increasing intestinal absorption of iron via upregulation of DCytoB and DMT1 and downregulation of hepcidin [13]. HIF-mediated regulation of hepcidin is dependent on EPO-stimulated erythropoiesis. HIF-2 upregulates ferroportin during iron deficiency in the small intestine and increases the capacity of basal iron transport. HIF-2 activation in the small intestine binds to hypoxia response elements of apical iron absorption genes.

### Altered iron balance and iron homeostasis in CKD

Iron is a vital component of human cellular physiology. Under physiologic conditions, iron is regulated in a closed system, with 1–2 mg/day iron absorbed to balance the iron lost [14]. Total body iron content is approximately 2–5 g and is much higher than the daily turnover (Fig. 38.2). Ferroportin, the transmembrane efflux channel, serves as the exporter of iron from enterocytes, macrophages, and hepatocytes. Patients with CKD, especially those on dialysis, showed marked alterations in iron balance and tissue iron distribution because of reduced iron absorption, increased iron losses, and impaired utilization of iron from body stores, thus giving rise to anemia. The amount of gastrointestinal blood loss was estimated at least three times higher in CKD patients and six times higher in dialysis patients than in non-CKD controls [15,16]. Patients on hemodialysis (HD) experienced

TABLE 38.1 Factors regulating hepcidin expression.

Factors upregulate hepcidin	Factors downregulate hepcidin
• Inflammation	• Hypoxia
• Infection	• Decreased hepatic iron
• Intravenous iron administration	• Decreased TSAT
• Increased hepatic iron	• Testosterone
• Increased TSAT	• Pregnancy

TSAT, Transferrin saturation.

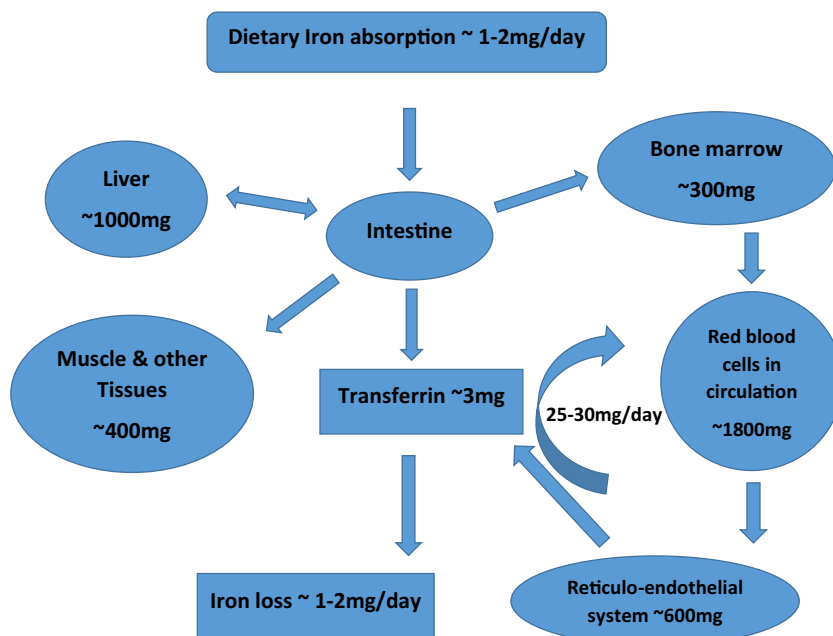

FIGURE 38.2 Iron homeostasis in health subject. Values in figure are estimations and may vary between subjects.

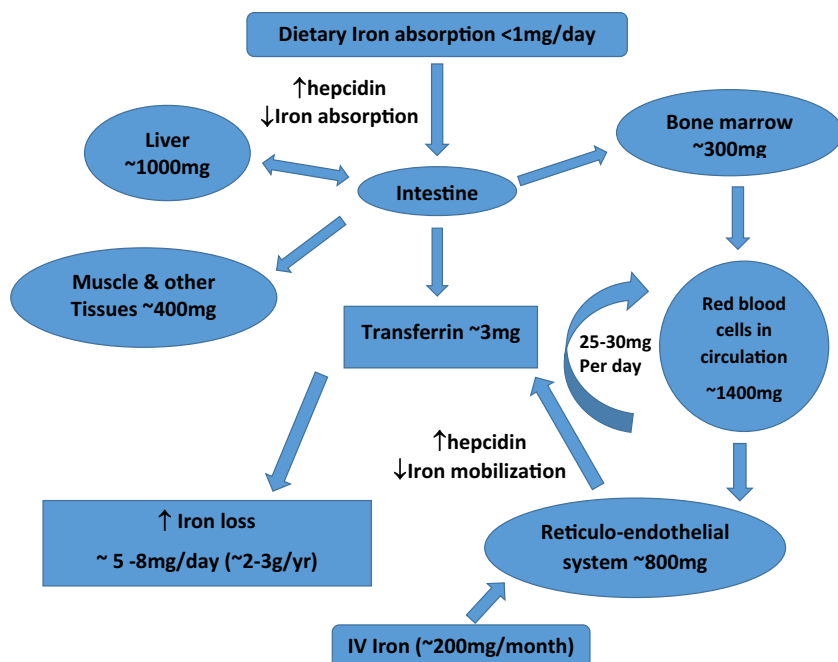

Patients with CKD also have reduced dietary iron intake and absorption. Decreased protein intake due to poor appetite with implementation of low-protein diets may result in reduced iron availability for absorption. Some medications may inhibit iron absorption from the gut such as proton pump inhibitors. CKD patients also exhibit reduced availability of stored iron as hepcidin levels are greatly increased. Hepcidin levels of CKD subjects and those on HD were reported to be three- to fivefold higher and may be up to ninefold higher compared with healthy controls. Hepcidin levels in CKD patients may increase due to chronic inflammation, infections, or reduced renal clearance of hepcidin. The increased hepcidin levels reduced iron availability and mobilization from storage and may explain resistance to ESA treatment or restricted erythropoiesis.

status, and heavy alcohol intake [20]. Study in HD subjects showed that TSAT and serum ferritin correlated poorly with magnetic resonance imaging (MRI)-assessed liver iron content and are poor indicators of body iron stores [21]. Thus it should not be used alone to assess iron status or guide iron therapy [22].

### Percentage of hypochromic red blood cells and the reticulocyte hemoglobin content

Both percentage of hypochromic red blood cells (% HRCs) and hemoglobin content (CHr) estimate the Hb content of red blood cells (RBCs) and not the amount of stored iron. They are more sensitive indicators of functional iron deficiency and possibly better than serum iron, TSAT, and serum ferritin in predicting response to iron administration. A metaanalysis performed for the 2016 National Institute for Health and Care Excellence guidelines demonstrated that % HRC > 6% was the most cost-effective strategy (least cost and most quality-adjusted life years) and has high specificity (95%) in predicting patients who would respond to iron. Its specificity is similar to using TSAT < 20% and ferritin < 100 ng/mL (98%). The negative predictive value was better with % HRC compared with TSAT and ferritin [23]. However, the studies comprising the metaanalysis are limited, and comparisons with TSAT < 20% and ferritin > 100 ng/mL are lacking. Furthermore, % HRC has to be tested within 6 hours of blood collection and CHr is time sensitive to the maturation of erythrocytes and cannot be used in subjects with thalassemia [24]. Thus more evaluations of these two parameters are required before they can be applied for routine clinical use.

### Hepcidin

Hepcidin is a negative regulator of iron availability and hypoferric-inducing hormone that increases with inflammation but is not a useful marker to assess iron stores. Although hepcidin has been shown to correlate with serum ferritin levels in some CKD patients [25], there were no consistent relationships observed between serum hepcidin and iron responsiveness in CKD or dialysis patients [26,27].

### Iron deficiency

Iron deficiency may occur in the setting of decreased, normal, or increased total body iron. The definition of iron deficiency may fall into two categories: absolute or functional. CKD patients with reduced total body iron stores have absolute iron deficiency if left untreated. Functional iron deficiency occurs in the

setting of normal or increased total body iron stores but iron delivery to the bone marrow was inadequate due to impaired iron mobilization from the reticuloendothelial system (RES) and/or increased bone marrow iron demand due to ESA treatment. Among patients with functional iron deficiency, iron sequestration in the RES occurs in the setting of inflammation of which patients have high ferritin levels but low TSAT (transferrin as a negative acute-phase protein) and erythropoiesis was restricted due to high hepcidin levels and reduced iron availability.

By convention, a serum ferritin level  $\leq 100 \mu\text{g/L}$  (100 ng/mL) in CKD and peritoneal dialysis, and a serum ferritin  $\leq 200 \text{ ng/mL}$  with a TSAT  $\leq 20\%$  in HD is usually used as the cut-off to define absolute iron deficiency, although a TSAT of  $>20\%$  does not exclude iron deficiency [15]. Functional iron deficiency or anemia of chronic disease is characterized by TSAT  $\leq 20\%$  and elevated ferritin levels  $\geq 800 \text{ ng/mL}$ . Patients with ESA-induced functional iron deficiency may respond to IV iron, in association with a concomitant increase in ESA dose with a decrease in ferritin levels.

### Associations between iron deficiency and clinical outcomes

Absolute iron deficiency was associated with a modest increase in 1- and 2-year cardiovascular hospitalization risk but not with mortality or dialysis initiation risk, as shown in recent observational analysis [2]. Functional iron deficiency was also associated with a modest increased risk of all-cause mortality and cardiovascular hospitalization while serum ferritin level  $>500 \text{ ng/mL}$  was associated with an increased risk of mortality [2]. Similarly, another retrospective analysis based on the US Veterans Data showed increased mortality with abnormal iron status in both diabetic and nondiabetic predialysis CKD subjects. Both high and low iron levels were associated with increased risk of mortality but the mortality risk was the highest among subjects with functional iron deficiency. However, it is important to take note that the study stratified iron groups based on joint quartiles of TSAT and ferritin and not using conventional clinical thresholds to define iron status [28].

### Iron management in CKD

KDIGO 2012 guideline suggested iron prescription should balance the potential benefits of avoiding or minimizing blood transfusions, ESA therapy, and anemia-related symptoms against the risks of harm in

individual patients (not graded). A trial of IV iron (for dialysis patients with anemia not on iron or ESA therapy) or alternatively a 1- to 3-month trial of oral iron therapy (for nondialysis CKD patients) is suggested if an increase in Hb concentration without starting ESA treatment is desired, and TSAT  $\leq$  30% and serum ferritin level  $\leq$  500 ng/mL ( $\leq$  500 mg/L) (2C). KDIGO guideline also suggested that for nondialysis CKD patients who require iron supplementation, route of iron administration should be selected based on the severity of iron deficiency, availability of venous access, response and side effects to previous oral iron therapy, patients compliance, and cost (not graded) [18].

On the other hand, the European Renal Best Practice (ERBP) guideline suggested a trial of iron therapy either IV or oral as a first step in nondialysis CKD patients, especially in CKD 2–3, or in PD patients with anemia if absolute iron deficiency (defined as TSAT  $<$  20% and serum ferritin  $<$  100 ng/mL) or an increase in Hb without starting ESA treatment is desired (with TSAT  $<$  25% and serum ferritin  $<$  200 ng/mL in nondialysis CKD patients, and with TSAT  $<$  25% and serum ferritin  $<$  300 ng/mL in dialysis patients). Following iron treatment, TSAT should not intentionally exceed 30% and serum ferritin should not exceed 500 ng/mL in both CKD and dialysis patients. For adult CKD patients on ESA therapy who are not receiving iron, a trial of IV iron is suggested if an increase in Hb or a decrease in ESA dose is desired and TSAT  $<$  30% and ferritin  $<$  300 ng/mL. In nondialysis CKD patients, oral iron should be started as a first step if tolerated. In HD patients a course of IV iron may be considered in those having higher serum ferritin levels in the presence of hyporesponsiveness to ESA or a risk/benefit ratio going against ESA use. Caution is suggested not to exceed a ferritin value of 500 ng/mL during combined iron and ESA treatment in dialysis patients, especially in those patients with adequate TSAT  $>$  30%.

Many HD patients with TSAT of 20%–30% and serum ferritin 200–500 ng/mL respond to iron supplementation with increase in Hb and/or reduction in ESA dosage. In the recent PIVOTAL trial, over a median of 2.1 years follow-up, HD patients randomized to high-dose proactive IV iron showed a 15% lower risk [95% confidence intervals (CI), 0.73–1.00] of primary composite endpoint event (which included nonfatal myocardial infarction, nonfatal stroke, hospitalization for heart failure, or death), as compared with the low-dose reactive IV iron group ( $P < .001$  for noninferiority;  $P = .04$  for superiority). In an analysis that used a recurrent-events approach, the finding remained consistent in that high-dose group was superior to low-dose group (hazard ratio, 0.77; 95% CI, 0.66–0.92). The infection rate as secondary endpoint was the same in both

groups. According to the protocol, subjects randomized to the high-dose proactive group received IV iron 400 mg monthly, unless ferritin  $>$  700  $\mu$ g/L or a TSAT  $\geq$  40%. Subjects randomized to low-dose reactive group received 0- to 400-mg IV iron monthly, with a ferritin  $<$  200  $\mu$ g/L or a TSAT  $<$  20% being a trigger for iron administration. In the trial, patients in the high-dose group received a median monthly iron dose of 264 mg [interquartile range (IQR), 200–336], as compared with 145 mg (IQR, 100–190) in the low-dose group. The median monthly ESA dose was 29,757 IU in the high-dose group and 38,805 IU in the low-dose group (median difference, –7539 IU; 95% CI, –9485 to –5582). The trial demonstrated that high-dose IV iron administered proactively was superior to a low-dose regimen administered reactively in lowering primary composite of nonfatal myocardial infarction, hospitalizations for heart failure, nonfatal stroke, and death events and resulted in lower doses of ESA administered. Furthermore, high-dose IV iron administered proactively appeared to protect against recurrent events and had fewer blood transfusions [29]. These quality data suggested that high-dose IV iron should be used more proactively in dialysis patients to reduce the dose of ESA or even prior to starting treatment with an ESA and raise the need to redefine the thresholds to initiate iron therapy in the dialysis population.

### Oral and IV iron

Oral iron is cheaper but has more gastrointestinal side effects especially constipation and also lower bioavailability. However, it should still be the first-line therapy in nondialysis CKD and peritoneal dialysis patients. Table 38.2 outlined the different oral iron formulations used to correct iron-deficiency anemia in CKD. Each contains different amount of elemental iron. Absorption of ferrous iron preparations is usually 10%–15% while that of ferric iron preparations may be three to four times lower because ferric iron is poorly soluble in the alkaline environment of the gut. IV iron is given in larger doses, has better efficacy and generally better tolerated than oral iron with less gastrointestinal side effects. Table 38.3 summarized the various IV iron formulations. A systematic review, including 28 randomized studies and quasirandomized studies comparing IV versus oral iron, showed that CKD patients treated with IV iron had greater increase in Hb, serum ferritin, and TSAT than oral iron. Dialysis patients receiving IV iron showed significant reduction in ESA dose. However, there were more hypotensive and allergic reactions with IV iron [30]. Another recent updated systematic review of randomized controlled trials (RCTs) showed similar findings in CKD stages 3–5 and

TABLE 38.2 Oral iron formulations.

Oral formulations	Salt content per tablet (mg)	Elemental iron per tablet (mg)	Recommended elemental calcium dose
Ferrous sulfate (generic)	325	65	200 mg/d
Ferrous gluconate	37.5	37.5	200 mg/d
Ferric citrate	1000	210	630 mg/d
Ferric citrate hydrate	250	45	90 mg thrice-daily
Ferric fumarate	325	106	200 mg/d
Ferric maltol	30	30	30 mg twice-daily
Liposomal iron	30	30	30 mg/d
Heme iron polypeptide	12	12	36–48 mg/d

TABLE 38.3 Intravenous iron formulations.

Intravenous formulation	Test dose	Molecular weight (Da)	Iron concentration (mg/mL)	Maximum daily dose
Iron dextran	Yes	265,000	50	100 mg
Low-molecular-weight iron dextran	Yes	165,000	50	100 mg
Iron sucrose	No	34,000–60,000	20	CKD: 200 mgHD: 100 mgPD: 300–400 mg
Sodium ferric gluconate complex in sucrose	No	289,000–444,000	12.5	125 mg
Ferumoxytol	No	750,000	30	510 mg
Ferric carboxymaltose	No	150,000	50	750 mg if body weight >50 kg15 mg/kg if body weight <50 kg
Iron isomaltoside	No	150,000	100	20 mg/kg

CKD, Chronic kidney disease; HD, hemodialysis; PD, peritoneal dialysis.

5D patients that IV iron was more effective and more likely to have Hb increase >1 g/dL. Safety analysis showed similar mortality rates, serious and any adverse effect rates with oral or IV iron. IV iron was associated with fewer gastrointestinal adverse effects but higher risk of hypotension. IV iron preparations examined in the randomized trials included iron sucrose, ferric carboxymaltose (FMC), ferrumoxytol, iron dextran, ferric citrate, and ferric gluconate [31]. These data support increased use of IV iron in patients with CKD 3–5D. However, the follow-up study was limited to 3 months and there was significant heterogeneity between trials.

## Potential risks of iron

### Hypersensitivity

Different iron preparations may differ in their adverse effects. Some older formulations such as iron dextran have higher risk of life-threatening

hypersensitivity or anaphylactic reactions and there is a strong consensus from the KDIGO 2012 Controversies Conference Report not to use these kinds of formulations. Newer iron formulations, for example, lower molecular weight iron dextran, FCM, iron isomaltoside 1000, and ferumoxytol that have much lower hypersensitivity reaction risk and doses can be infused more rapidly within 15–60 minutes would be preferred in nondialysis CKD and dialysis patients. These formulations may be superior to oral iron supplementation in enabling more cost-effective iron and anemia management in nondialysis CKD and dialysis population. Minor infusion reactions are common with IV iron infusion and may include symptoms of flushing, light-headedness, dizziness or mild chest discomfort, nausea, or itching. Sometimes asymptomatic hypotension may develop and some patients may develop myalgia or arthralgia. These symptoms are usually self-limiting and do not require treatment. These mild infusion reactions usually resolve when infusion is stopped or infusion rate is

slowed down and generally do not preclude further IV iron administration.

## Iron overload

Iron overload represents a condition with increased total body iron stores that may result in body organ dysfunction. There is currently no unified definition of iron overload and how to assess iron overload in CKD patients. Serum ferritin, when elevated, may not always reflect increased total body iron stores and does not correlate with liver iron content, as it may increase as an acute-phase reactant. However, a high TSAT level together with a high serum ferritin level may be a concern for iron overload, as shown in transfusion-related iron overload and hereditary hemochromatosis.

CKD patients frequently had increased serum ferritin as a result of upregulation with inflammation. In the general population, high serum ferritin was associated with an increased risk of myocardial infarction and carotid plaque. In an observational study of 58,058 HD patients, high serum ferritin >800 ng/mL was associated with an increased mortality, but this association was markedly attenuated with adjustment for malnutrition and inflammation [32], suggesting that hyperferritinemia may relate to inflammation. Another analysis from the US, Japan, and European Dialysis Outcomes and Practice Patterns Study (DOPPS) showed similar findings that high ferritin levels were associated with elevated mortality risk but the association was attenuated more by adjustment for malnutrition and inflammation than by IV iron and ESA dose [33]. On the other hand, another observational study based on Japanese HD patients participated in the DOPPS III (2005–08) or DOPPS IV (2009–12) showed that serum ferritin level was associated with cardiovascular hospitalization regardless of inflammatory conditions. However, a U-shaped association was observed between serum ferritin and all-cause mortality in the group with low CRP levels and no association was observed in the high CRP group [34]. These data suggest limitation of using serum ferritin alone as a marker reflecting excess iron stores.

MRI provides a reliable estimate of tissue iron content in non-CKD populations [35]. Study in HD patients receiving ESA and IV iron treatment showed that most had increased liver iron content [36]. However, most peritoneal dialysis patients had normal liver iron content by MRI [37]. The clinical value of MRI in diagnosing iron overload and guiding iron therapy in CKD and dialysis patients need further evaluation.

## Infections

Iron plays an important role in bacterial multiplication and phagocytic function. In vitro studies showed the association between iron availability and bacterial virulence. However, clinical studies examining associations between iron stores, IV iron dosing, and bacteremic or infection risk have produced variable results [24,38,39]. Among the nine observational studies that evaluated associations between serum ferritin and infection risk, there was generally a 1.5- to 3.1-fold higher risk of bacterial infection or infection-related mortality. This translated to an excess of 16–50 bacterial infections per 100 patient-years among those with higher serum ferritin. On the other hand, several studies did not observe any relations between serum ferritin and infection risk.

The way of IV iron administration has long been regarded to impact infection rates. A large US dialysis provider examined the iron dosing patterns of 117,050 HD patients during repeated 1-month exposure on risks of mortality and infection-related hospitalizations in the subsequent 3 months. Results showed that patients receiving bolus iron were at increased risk of infection-related hospitalization compared to maintenance iron. Risks were the highest among patients with a catheter and a recent infection. Bolus dosing was also associated with an increased risk of infection-related mortality. However, maintenance dosing did not increase risks of adverse outcomes [40]. Another retrospective analysis based on a large US dialysis provider showed that among end-stage kidney disease patients aged  $\geq 65$  years who started and survived first 90 days of in-center HD, those receiving more intensive iron treatment at moderate-to-high iron indices levels were associated with higher risks of mortality and infection-related events than those receiving less intensive iron strategies [41]. The KDIGO 2012 Clinical Practice Guideline suggested to avoid IV iron in patients with active systemic infections. At the time, the statement was ungraded due to lack of high-quality evidence [15]. The recent PIVOTAL RCT did not show any difference in adverse events in terms of the rates of hospitalizations due to infections and rates of all episodes of infections between high- and low-dose IV iron sucrose in HD patients [29]. A prespecified secondary analysis of PIVOTAL trial confirmed no difference in any infection, hospitalization for infection, and death from infection rates, confirming safety with higher dose IV iron administration in dialysis patients [42]. Similarly, another randomized trial did not observe any difference in infection rates between subjects receiving IV FMC and oral iron over 56 weeks [25]. The more recent studies provide safety reassurance of using higher doses of IV iron in the dialysis population.

## Oxidative stress

Early studies raised the biological plausibility that IV iron may increase oxidative stress to peripheral leukocytes [43], promote protein oxidation [44] and lipid peroxidation [45], and thus promote atherosclerosis [46]. Iron sucrose aggravated early atherosclerosis by increasing monocyte adhesion to endothelium and promoting endothelial dysfunction in a remnant kidney model [47]. However, another animal model of accelerated atherosclerosis did not observe similar findings [48]. Although observational data suggested iron doses more than 400 mg/month may increase cardiovascular death rates [32], the prospective randomized PIVOTAL trial showed that proactive IV iron significantly reduces the risk of nonfatal myocardial infarction, nonfatal stroke, and hospitalizations for heart failure and mortality in dialysis patients compared to low-dose IV iron and did not increase cardiovascular risk [29]. This reaffirms cardiovascular safety of higher doses of IV iron in dialysis patients.

## Effects on iron on CKD—mineral bone disease

Certain IV iron preparations, for example, FMC and ferric citrate, may alter CKD—mineral bone disease (MBD) parameters. For example, study showed that short-term use of ferric citrate may be associated with reduced FGF-23, serum phosphate, and urine phosphate excretion in CKD [49]. Further analysis showed that ferric citrate reduced FGF-23 partly via its effect on serum phosphate and iron balance and did not reduce serum phosphate among subjects with normal serum phosphate [50]. FMC, but not ferumoxytol, also induced circulating biologically active FGF23, renal phosphate wasting, and hypophosphatemia; decreased serum calcitriol and calcium; and increased intact parathyroid hormone (iPTH) concentrations in subjects with iron-deficiency anemia and normal kidney function [51]. Another prospective multicenter double-blind RCT in the US compared a single course of IV FMC versus ferumoxytol in adults with iron-deficiency anemia and normal kidney function over a 5-week period. The trial confirmed that FMC but not ferumoxytol rapidly increased biologically active FGF23 with renal phosphate wasting, calcitriol deficiency, and secondary hyperparathyroidism that frequently culminates in hypophosphatemia [52]. These data suggest the need to monitor for hypophosphatemia with IV iron administration, especially ferric citrate and FMC that cause hypophosphatemia.

## Management of renal anemia

### Erythropoietin-stimulating agents

In 1989 the US Food and Drug Administration (FDA) approved the use of recombinant EPO for renal anemia and in the last 20 years, this class of drug has revolutionized anemia management in CKD. However, these agents are not without side effects in that they may cause hypertension. More importantly, several previous RCTs raised safety concerns with these agents, resulting in several black box warnings from FDA. These trials showed that raising hematocrit to normal levels (target of 42%) or raising Hb to normal levels (13.5 g/dL) increased the risk of death or first nonfatal myocardial infarction [53], or risk of composite death and cardiovascular events [54]. Another RCT reported similar findings that correction of anemia to 13 g/dL with darbepoetin alfa may increase risk of stroke in diabetic CKD patients [55]. Additionally, there is data to suggest that a poor initial hematopoietic response to darbepoetin alfa was associated with an increased risk of death or cardiovascular events, as doses were escalated to meet the target Hb level [56]. The exact explanation for the increased adverse cardiovascular outcomes with correction of anemia is currently unclear but may relate to the doses of EPO administered and the clinical conditions that cause EPO hyporesponsiveness. Furthermore, safety concerns were raised that high-dose ESA treatment may promote angiogenesis and tumor growth and increased adverse events and outcomes [57].

A nationwide registry-based cohort study in Japan comparing the mortality risk associated with short-acting versus long-acting ESA in 194,698 HD patients showed that long-acting darbepoetin alfa and methoxy polyethylene glycol-epoetin beta were associated with a 20% higher mortality risk than short-acting ESAs such as epoetin alfa, beta, and kappa. The association was attenuated but remained significant after adjusting for demographics, clinical factors, facility indicators, and, when considered, a propensity score-matched cohort. Notably, the difference in risk was higher among those receiving higher ESA doses and those with a high erythropoietin resistance index. Furthermore, the use of long-acting ESA was associated with an increased rate of death from cardiovascular disease, infections, and malignancies [58]. However, the study was retrospective and data were not generalizable to populations other than the Japanese. As the US FDA and the European Medicines Agency required confirmation of cardiovascular safety of ESA particularly when aiming for higher Hb levels, a large randomized postapproval noninferiority trial was performed in 2818 dialysis and nondialysis CKD

patients to compare all-cause mortality and cardiovascular events of methoxy polyethylene glycol-epoetin beta versus other ESAs. The results showed that methoxy polyethylene glycol-epoetin beta was not associated with increased risk of all-cause mortality and major adverse cardiovascular events (MACE) compared to other ESAs [59].

Recent randomized trial examined whether targeting Hb level of 11–13 g/dL using darbepoetin alfa may affect kidney outcomes compared to a lower Hb target of 9–11 g/dL in nondiabetic advanced CKD subjects in Japan. The eGFR of study subjects ranged between 8 and 20 mL/min/1.73 m<sup>2</sup>. The primary study outcome was a kidney composite endpoint (starting maintenance dialysis, kidney transplantation, eGFR ≤ 6 mL/min/1.73 m<sup>2</sup>, and 50% reduction in eGFR). The results showed that the kidney composite endpoint and cardiovascular events did not differ between the high- and low-Hb groups during a mean study period of 73.5 ± 29.7 weeks [60].

### HIF propyl hydroxylase domain inhibitors

With the discovery of a major transcription factor HIF for the EPO gene in 1992, drugs that inhibit the HIF PHD were developed. This class of drugs called HIF stabilizers or PHD inhibitors prevents the proteasomal degradation of HIF- $\alpha$ , thus induces the EPO gene. During hypoxia, PHDs are less active and HIF- $\alpha$  can bind to HIF- $\beta$  subunit, translocate into the nucleus, and induce a physiological response to hypoxia. It induces the EPO gene and stimulates erythropoiesis, increases intestinal absorption of iron and mobilization of iron, and coordinates other cellular responses, including angiogenesis, lipid and glucose metabolism, mitochondrial function, cell growth and survival, vasodilatation, cell migration, and inflammation (Fig. 38.1).

PHD inhibitors mimic the response with hypoxia, stabilize HIF- $\alpha$ , and are oral drugs. They stimulate endogenous EPO production from native kidneys or the liver. PHD inhibitors also change iron metabolism. They markedly reduce hepcidin and effectively maintain Hb levels with less iron need and correct anemia in inflamed CKD patients with functional iron deficiency. They also reduce ferritin and increase total iron-binding capacity in CKD [61]. There are currently five PHD inhibitors, roxadustat, daprodustat, vadadustat, molidustat, and enarodustat and phase III trials with these PHD inhibitors are currently in progress in different parts of the world. Phase II trials of all these drugs with various follow-up durations showed a dose-dependent improvement in erythropoiesis and anemia.

In a multicenter open-label phase IIb study conducted in anemic nondialysis CKD patients, 92% achieved the required Hb response (i.e., Hb ≥ 1 g/dL from baseline and Hb ≥ 11 g/dL) after 16 weeks roxadustat (FG-4592 or ASP1517) treatment. Hepcidin levels decreased by 16.9%. Roxadustat-induced Hb increases were independent of C-reactive protein levels and iron repletion status. Furthermore, there was a reduction in total cholesterol level and no serious drug-related adverse events [61].

A multicenter randomized open-label active-controlled phase III trial has recently confirmed safety and efficacy of oral roxadustat in dialysis patients of which nearly 90% were HD and 10% were peritoneal dialysis. The study recruited 304 dialysis patients receiving ESA therapy for at least 6 weeks and patients were randomized in a 2:1 ratio to receive either oral roxadustat or subcutaneous epoetin alfa three times a week for 26 weeks with the primary endpoint being the mean change in Hb level from baseline to an average level during weeks 23–27. The results showed that oral roxadustat was noninferior to parenteral epoetin alfa in increasing Hb level. Furthermore, oral roxadustat was associated with a greater increase in iron and TSAT than parenteral epoetin. Furthermore, roxadustat was associated with significantly greater reduction in serum hepcidin levels, total cholesterol and LDL-cholesterol levels. However, hyperkalemia and upper respiratory tract infection occurred at a higher frequency with roxadustat than epoetin alfa while hypertension occurred at higher frequency with epoetin alfa [62]. In another phase III trial conducted at 29 sites in China, 154 nondialysis CKD patients with Hb between 7.0 and 10.0 g/dL were randomized to receive roxadustat or placebo three times a week for 8 weeks in a double-blind fashion followed by an 18-week open-label period during which all patients received roxadustat and parenteral iron was withheld. In the primary analysis, roxadustat group had greater increase in Hb levels than placebo. Roxadustat group showed more reduction in serum hepcidin and total cholesterol levels than placebo group. Hyperkalemia and metabolic acidosis occurred more frequently in roxadustat than placebo group. The efficacy of roxadustat in correcting Hb was maintained throughout the 18-week open-label period [63].

A recent systematic review, including 6 RCTs that comprised 1001 patients of which 70.6% were treated with roxadustat and 294 controls and with a median follow-up of 8 weeks, concluded that roxadustat increases Hb, serum transferrin, intestinal iron absorption, and reduces hepcidin in both dialysis and nondialysis CKD patients [64]. In a pooled efficacy and cardiovascular safety analysis by Provenzano et al., roxadustat was superior to epoetin alfa in anemia

correction and maintenance of Hb, and comparable to epoetin alfa in its cardiovascular safety profile. Event risk for MACE and mortality was similar for nondialysis CKD and prevalent dialysis patients randomized to roxadustat or placebo/epoetin alfa. In incident dialysis patients, roxadustat was associated with a reduced risk of first MACE, heart failure, and unstable angina requiring hospitalization than epoetin alfa [65].

Similarly, a 4-week phase IIa trial and a 24-week open-label trial with daprodustat (GSK1278863) showed that daprodustat effectively increased and maintained Hb during the study period [66,67]. A 6-week phase IIa trial and a 20-week phase IIb trial with vadadustat (AKB-6548) have reported similar findings of a dose-dependent increase in Hb in nondialysis CKD patients [68,69]. Molidustat (BAY 85-3934), a novel selective oral HIF PHD inhibitor, has also been evaluated in three 16-week, phase IIb studies in anemic nondialysis CKD patients [Daily orAL treatment increasing endogenous Erythropoietin (DIALOGUE) 1 and 2] and in dialysis patients (DIALOGUE 4). Molidustat was generally well tolerated and associated with estimated mean Hb levels increase of 1.4–2.0 g/dL [70]. Recent extension study of DIALOGUE showed that molidustat was well tolerated up to 36 months and was a comparable alternative to darbepoetin and epoetin alfa as a treatment for anemia in CKD [71]. These data form an important basis for further phase III trials of the different PHD inhibitors.

## Potential adverse effects of PHD inhibitors

PHD inhibitors have diverse physiological actions beyond stimulation of endogenous EPO production. The activation of HIF and the increase in VEGF are worrisome for possible risks of promoting angiogenesis, tumor growth, or diabetic retinopathy [72]. HIF activation may also cause new onset or exacerbate pulmonary hypertension [73]. Thus further RCTs are required to evaluate the long-term safety profile of this class of novel therapeutic drugs for anemia.

## Initiation and maintenance treatment with ESA

### Initiation of ESA therapy

According to KDIGO 2012 guideline, all correctable causes of anemia, including iron deficiency, B12, folate deficiency, and inflammatory states, should be addressed before initiation of ESA. In initiating and maintaining ESA therapy, KDIGO recommended the potential benefits of reducing blood transfusions and anemia-related symptoms should be balanced against the risks of harm in individual patients (e.g., stroke,

vascular access loss, and hypertension) (1B). KDIGO recommended great caution with ESA therapy in CKD patients, if at all, with active malignancy, in particular when cure is the anticipated outcome (1B), a history of stroke (1B) or a history of malignancy (2C) [22]. The ERBP felt that these issues should take into account when weighing the risk/benefit ratio of prescribing ESA therapy. However, they are not absolute contraindications to ESA treatment and nephrologists should discuss them with each patient, balancing the risk versus benefit [74].

For adult nondialysis CKD patients with Hb < 10.0 g/dL, KDIGO suggested the decision whether to initiate ESA therapy be individualized based on the rate of fall of Hb level, prior response to iron therapy, the risk of blood transfusion, the risks related to ESA therapy and the presence of symptoms attributable to anemia (2C). KDIGO suggested ESA therapy should not be initiated in CKD patients with Hb ≥ 10 g/dL.

The ERBP suggested to individualize initiation of ESA therapy in nondialysis (ND)-CKD and not to allow Hb to fall < 10 g/dL in ND-CKD patients. Furthermore, ESA therapy should not be initiated if there is a temporary and obvious potential reversible cause of anemia identified such as iron deficiency, bleeding, infections, or inflammations. ERBP also stratified management for low- and high-risk patients. For high-risk patients, including those with asymptomatic ischemic heart disease, ESA should be initiated at Hb between 9 and 10 g/dL to maintain Hb level of > 10 g/dL. In low-risk patients or those in whom a clear benefit on quality of life can be foreseen, ESA could be initiated at higher Hb levels (but not > 12 g/dL) [74].

For adult dialysis patients, KDIGO suggested ESA therapy should be used to avoid having Hb level fall below 9.0 g/dL by starting ESA therapy when Hb is between 9 and 10 g/dL (2B). It is not entirely certain why slightly different threshold was applied in the initiation of ESA therapy for nondialysis and dialysis CKD patients by KDIGO. However, KDIGO suggested that individualization of ESA therapy is reasonable and ESA may start above 10 g/dL if some patients may have improvement in quality of life at higher Hb levels (ungraded) [22]. Similarly, ERBP suggested to individualize ESA therapy in dialysis CKD patients. Hb should not fall < 10 g/dL in CKD 5D patients. In low-risk patients, in those with ischemic heart disease and worsening ischemic symptoms associated with anemia, or in those in whom a clear benefit on quality of life can be foreseen, ESA therapy could be initiated at higher Hb level but not exceed 12 g/dL. In high-risk patients, ESA therapy could be initiated at Hb between 9 and 10 g/dL to maintain a target Hb level of 10 g/dL

[74]. We summarize the various clinical practice guidelines on the Hb thresholds and targets in initiation and maintenance of ESA therapy, respectively in Table 38.4.

## Maintenance of ESA therapy

KDIGO 2012 suggested that ESA therapy should not maintain Hb above 11.5 g/dL in adult CKD (2C) and not above 13 g/dL in all adults (1A). Individualization of therapy will be necessary as some patients may have improvements in quality of life at Hb level >11.5 g/dL and will be prepared to accept the risks (not graded). Furthermore, decreasing ESA dose is preferred to withholding ESA when a downward adjustment of Hb concentration is needed (2C) [22]. ERBP suggested ESA therapy should generally maintain Hb levels between 10 and 12 g/dL in CKD patients but should individualize the value within this target range according to comorbidities of patients. Caution should be used in patients with specific risk factors especially among diabetics with vascular disease, cancer, or in those who are hyporesponsive to ESA treatment, and in these patients, it is better to aim toward the lower

Hb levels within the range between 10 and 12 g/dL. ERBP also made a similar statement as KDIGO that Hb should not intentionally aim >13 g/dL during ESA therapy [74].

The rationale for being cautious of a higher Hb target and setting a lower Hb target in the maintenance phase of ESA therapy by the different guideline bodies was based on the results of several large clinical trials showing that complete anemia correction has no benefit but may incur an increased risk of death and cardiovascular events.

## ESA hyporesponsiveness

Approximately 5%–10% of patients with CKD demonstrated hyporesponsiveness to ESA [75]. Conventionally, this is defined as a continued need for greater than 300 IU/kg/week EPO or 1.5 mg/kg/week darbepoetin administered by subcutaneous route. CKD patients with ESA hyporesponsiveness were noted to have a worse clinical outcome, greater risk of mortality, and more progression to ESRD [76]. KDIGO 2012 classified patients as having ESA hyporesponsiveness if they have no increase in Hb level from baseline after

**TABLE 38.4** Clinical practice guidelines on initiation and maintenance of erythropoietin-stimulating agent (ESA) therapy in chronic kidney disease.

	KDIGO 2012	ERBP 2012
Initiation of ESA therapy	Individualize ESA initiation based on rate of fall in Hb, prior response to iron, risk of blood transfusion, risk related to ESA therapy, and presence of symptoms attributable to anemia	
• Nondialysis CKD	Initiate ESA therapy if Hb < 10 g/dL (2C) Do not initiate ESA if Hb ≥ 10 g/dL (2D)	Hb should not fall <10 g/dL Low-risk patients—can consider starting ESA at higher Hb (but not >12 g/dL) High-risk patients—start ESA at Hb between 9 and 10 g/dL Patients with ischemic symptoms—ESA could start at higher Hb (>10 g/dL)
• Dialysis CKD	Initiate ESA when Hb between 9 and 10 g/dL Avoid Hb fall <9 g/dL (2B)	Avoid Hb fall <10 g/dL Low-risk patient—ESA could start at higher Hb but not exceed 12 g/dL High-risk patient—start ESA at Hb between 9 and 10 g/dL
Maintenance of ESA therapy	ESAs not be used intentionally to increase Hb >13 g/dL in all CKD (1A)	
• Nondialysis CKD	Hb with ESA treatment should not be >11.5 g/dL (2C) Individualize therapy as some patients may have improvements in quality of life at Hb >11.5 g/dL and prepare to accept the risks (ungraded)	Low-risk patient—maintain Hb between 11 and 12 g/dL High-risk patient—maintain Hb ~10 g/dL
• Dialysis CKD	Hb with ESA treatment should not >11.5 g/dL (2C) Individualize therapy as some patients may have improvements in quality of life at Hb >11.5 g/dL and prepare to accept the risks (ungraded)	Maintain Hb between 10 and 12 g/dL and individualize the value within this range according to comorbidities of patients High-risk patient—maintain Hb ~10 g/dL or lower end within this range

the first month of ESA treatment given on appropriate weight-based dosing (ungraded). In patients with ESA hyporesponsiveness, KDIGO suggested avoiding repeated escalations of ESA dose beyond double the initial weight-based dosing (2D).

There are many possible factors contributing to ESA hyporesponsiveness. These include inflammation, inadequate dialysis, hyperparathyroidism, nutrient deficiencies (vitamin B12, folate, vitamin C, carnitine), angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, aluminum overload, antibody-mediated pure red cell aplasia, primary bone marrow disorders, myelosuppressive agents, hemoglobinopathies, hemolysis, and hypersplenism. It is therefore important to look for these possible causes in case of ESA hyporesponsiveness. For the relevance of this chapter, we will discuss the nutritional factors that may contribute to ESA hyporesponsiveness. It includes deficiencies of vitamin B12, folate, vitamin C, and carnitine. We also discuss briefly the relations between vitamin D and anemia.

### Contributions of various other nutrition factors relating to anemia in CKD

#### Carnitine

Carnitine is an amino acid derivative synthesized by the essential amino acids lysine and methionine [77]. It plays an essential role in the  $\beta$ -oxidation of fatty acids by catalyzing their transport into the mitochondrial matrix, modulating the ratio of cellular and mitochondrial acyl CoA to free CoA, stabilizing cell membranes by removing long-chain acyl CoAs and excess acyl groups from the body [78]. Meat, fish, and dairy products are major dietary sources of L-carnitine, which are absorbed mainly in the small intestine via an active organic cation transporter [79]. Carnitine is also synthesized endogenously from trimethyllysine in the liver and the kidneys [80] but is concentrated in the cardiac and skeletal muscles, which depends on fatty acids for energy metabolism [81]. In addition to carnitine synthesis, the kidneys play an important role in carnitine homeostasis and maintaining carnitine concentrations within a narrow homeostatic range by saturable tubular reabsorption. The kidneys also play an important role in the esterification and excretion of carnitine [78]. Dialysis patients have reduced renal synthesis of L-carnitine and increased dialytic losses of carnitine, thus increasing their risk of carnitine deficiency. Vegetarians also excreted markedly less L-carnitine than omnivores as they had 10%–20% lower plasma L-carnitine concentration [82]. One study showed that L-carnitine levels decreased significantly

within the first week of HD initiation and continued to decline over the first 12 months of dialysis and could be attributed to increased dialysis clearance of carnitine [83]. The prevalence of carnitine deficiency, defined as a serum-free carnitine level  $<20 \mu\text{mol/L}$ , and that of carnitine insufficiency, defined as an acyl/free carnitine ratio  $>0.4$ , was estimated to be 25.3% and 86.7%, respectively, in one cohort. Patients at high risk of carnitine deficiency accounted for 64.7% [84]. Another study reported the prevalence of carnitine deficiency to be 8.8% and carnitine insufficiency 82.3% in peritoneal dialysis patients [85].

L-Carnitine deficiency may give rise to anemia, intradialytic hypotensive symptoms, muscle weakness and fatigue, impaired exercise capacity, cardiomyopathy, hyperlipidemia, and inflammation [81]. However, treatment with L-carnitine has not been proven to be useful in ameliorating these complications associated with CKD [81].

L-Carnitine deficiency may contribute to anemia by reducing erythrocyte membrane stability and increasing osmotic fragility, thus reducing erythrocyte survival [86]. Early study showed that serum total carnitine levels were inversely correlated with erythrocyte fragility and weekly erythropoietin doses in HD patients [87]. L-Carnitine supplementation may reduce red cell deformity, improve red cell membrane stability, and increase hematocrit [88,89]. Several RCTs did not observe any significant change in Hb with IV L-carnitine in chronic HD patients [90,91]. Existing randomized trials were mostly very small sample size, short duration, and dated. The doses of IV carnitine used were also variable ranging from 2 g to 25 mg/kg [89]. A multicenter double-blind randomized study in 92 incident HD patients showed that L-carnitine 1 g, given IV after each HD session for 1 year did not improve their response to EPO [92]. Putting together available evidence, IV carnitine is not a useful adjunctive therapy for anemia in HD patients. KDIGO 2012 suggested not using L-carnitine as an adjuvant to ESA treatment. Further large RCT will need to explore the full pharmacologic potential of IV carnitine.

#### Ascorbic acid

Ascorbic acid increases iron absorption from foods and is the most efficient promoter of nonheme iron absorption [93]. It maintains iron in a reduced state and promotes the enzymatic incorporation of iron into protoporphyrin, an intermediate in heme biosynthesis [94,95]. In HD patients, iron metabolism may be dysregulated with diminished utilization of iron stores. Ascorbic acid improves iron availability through its role in maintaining iron in a reduced state [96].

Subclinical ascorbic acid deficiency was reported in at least 30%–50% of dialysis patients [97,98]. Several factors may contribute to ascorbic acid deficiency, including restricted dietary intake of fruits and vegetables in dialysis patients and increased loss of ascorbic acid during dialysis. Epidemiologic studies suggested that low total ascorbic acid level was associated with an increased risk of all-cause death and cardiovascular mortality in HD patients [97,99]. Early study demonstrated that IV administration of high-dose ascorbic acid 300 mg thrice-weekly in HD patients treated with epoetin and serum ferritin >500 ng/mL increased hematocrit, serum iron, and TSAT [100], suggesting that IV ascorbic acid may improve iron utilization. Subsequent to this observation, several RCTs evaluated the efficacy of IV ascorbic acid in ESA-treated dialysis patients. Results of these trials were summarized in two systematic reviews [101,102]. The systemic review by Deved et al. combined three randomized trials and showed that ascorbic acid increased Hb, decreased ESA dose, and increased TSAT [101]. The other systematic review by Einerson et al. included five studies and concluded that adjuvant ascorbic acid increased Hb and TSAT in HD patients with EPO hyporesponsiveness. The significant rise in TSAT suggested that the positive response with EPO may relate to improved iron utilization with ascorbic acid treatment [102].

The latest National Kidney Foundation (NKF) Kidney Disease Outcome Quality Initiative (KDOQI) nutrition guidelines in CKD did not suggest ascorbic acid as adjuvant therapy for anemia in CKD. However, the guideline suggested that in adults with CKD 1–5D and posttransplant who are at risk of ascorbic acid deficiency, it is reasonable to consider supplementation to meet the recommended intake of at least 90 mg/d for men and 75 mg/d for women (opinion).

A potential concern with high-dose ascorbic acid treatment is oxalate accumulation [103]. The ascorbic acid dose required to increase iron mobilization from tissue stores and improve ESA responsiveness is much higher than the daily recommended dietary allowance [104]. As ascorbic acid is converted to oxalic acid that needs kidney function for clearance [105], it may accumulate in dialysis patients. Thus KDIGO does not suggest ascorbic acid as an adjuvant treatment for anemia in dialysis patients.

## Vitamin D

25-Hydroxyvitamin D deficiency and insufficiency are highly prevalent in dialysis and CKD population [106,107]. Epidemiologic studies in the general population as well in CKD have linked vitamin D deficiencies with anemia [108–110] and EPO responsiveness [111].

One potential mechanism may involve its action on the hepcidin–proinflammatory cytokines pathway [112]. Vitamin D is antiinflammatory [113]. In vitro study showed that treatment with calcitriol reduces inflammatory cytokine release, suppresses hepcidin mRNA expression, and increases ferroportin mRNA expression from monocytes, suggesting that vitamin D plays a regulatory role on the hepcidin-ferroportin axis [114,115]. By suppressing hepcidin expression and inflammation, vitamin D increases iron mobilization from tissue stores, promotes erythropoiesis, and improves anemia of inflammation [112].

Another mechanism that underlies the association between vitamin D and anemia of inflammation is through suppression of erythropoiesis. Inflammatory cytokines may suppress erythropoiesis by inhibiting the production of EPO and differentiation and proliferation of erythroid progenitor cells [116]. Vitamin D improves erythropoiesis by promoting proliferation of erythroid burst-forming units (BFU-E) and acts synergistically with EPO to increase BFU-E proliferation [117]. Adding vitamin D3 treatment to rats that received ribavirin as part of the hepatitis C treatment increased their Hb levels and increased EPO levels compared to rats that did not receive vitamin D3 [118], suggesting that vitamin D may protect against drug-induced disturbances in erythropoiesis. Vitamin D treatment also reduced ESA requirements in CKD patients [111,119].

Vitamin D and anemia are associated via other hormones in the CKD–MBD axis. Elevated PTH, a key derangement in CKD–MBD, causes osteitis fibrosa cystica and is associated with marrow fibrosis. Study showed that the degree of erythropoietin responsiveness depended both on the severity of secondary hyperparathyroidism and also the extent of marrow fibrosis [120]. Early animal study showed that iPTH inhibits erythropoiesis through reduction of erythroid progenitor formation and adequate levels of EPO can overcome this action of PTH [121]. PTH may also increase calcium influx into RBCs and affect osmotic fragility of these cells, thus reduce the survival of erythrocytes [122]. In clinical studies, elevated iPTH levels were associated with more anemia and increased odds of EPO resistance in CKD [123,124]. Uncontrolled studies showed that dialysis patients who underwent parathyroidectomy [125] or received cinacalcet treatment [126] to lower very high PTH levels had increases in Hb. This provides indirect evidence that severe secondary hyperparathyroidism contributes to anemia in CKD. Control of severe secondary hyperparathyroidism using vitamin D analogs has been shown to improve anemia and EPO responsiveness [127,128]. Treatment of secondary hyperparathyroidism may thus serve as a mechanism by which vitamin D treatment improves anemia in

dialysis patients. However, it is currently unknown whether this association is independent or dependent of vitamin D. KDIGO or NKF KDOQI did not recommend vitamin D as an adjuvant treatment for anemia in dialysis or nondialysis CKD patients.

Preliminary evidence suggested that FGF-23 and Klotho may be involved in erythropoiesis. Coe et al. showed that FGF-23 knockout mice had more erythrocytosis, more BFU-E proliferation, and higher serum EPO compared to wild-type mice. Notably, fetal livers had similar hematopoietic changes, suggesting that they were not the result of altered bone marrow niche alone. On the other hand, administration of FGF-23 in wild-type mice resulted in a rapid decrease in erythropoiesis. The effects of FGF-23 on erythropoiesis appeared independent of the high vitamin D levels in these mice. These data suggest FGF-23 may be a negative regulator of erythrocyte production and differentiation and may contribute to anemia in patients with CKD [129]. In line with this animal data, study also reported a negative correlation between Hb and FGF-23 in CKD subjects [130]. A Klotho knockout mouse model, Klotho being a necessary cofactor for FGF-23, had increased erythrocytosis along with increased BFU-E in bone marrow compared to wild-type and heterozygous mice though hematopoietic stem cells in the bone marrow were reduced [131].

FGF-23 is closely associated with iron homeostasis and iron deficiency has been suggested to be a key driver of FGF-23 [132]. Early study observed FGF-23 increase with reduction in iPTH with administration of low-molecular-weight iron dextran in HD patients [133]. The link between FGF-23 and iron was further demonstrated in a 12-week double-blind randomized placebo-controlled trial with ferric citrate in stages 3–5 CKD patients with iron-deficiency anemia [49]. Ferric citrate not only improved anemia and iron stores but also reduced serum phosphate, FGF-23, and urine phosphate excretion in nondialysis CKD [49]. Study

also showed that ferric citrate reduced FGF-23 and improved EPO responsiveness in HD patients [134]. Given elevated FGF-23 predicted an increased mortality and cardiovascular risk in CKD and dialysis patients [135,136], whether iron treatment by lowering of FGF-23 may improve outcomes of CKD warrant further evaluation. Table 38.5 summarized the various associations between CKD–MBD biomarkers, erythropoiesis, and iron indices.

## Folic acid

Folic acid is a key nutrient required for erythropoiesis. It serves as a cofactor for DNA synthesis and its requirement increases in the face of increased RBC turnover. Folic acid is also an effective treatment to lower hyperhomocysteinemia. The exact prevalence of folic acid deficiency in dialysis patients is not known. Some reports suggested a prevalence of folic acid deficiency of 10%–12% in HD patients [137]. Dialysis patients are at risk of folic acid deficiency due to dietary restriction of green leafy vegetables for potassium concerns. Folic acid is also lost during dialysis therapy particularly with high-flux dialysis [138]. Studies suggested that folic acid deficiency may mediate ESA resistance in dialysis patients and folic acid supplementation may reduce EPO requirement [139–141]. However, there are also reports that high-dose folate supplementation did not improve EPO responsiveness [142]. Folic acid has also not been shown to improve overall survival and cardiovascular outcomes of dialysis patients [143]. While it is important to evaluate serum B12 and folate levels in the initial evaluation of anemia [22], routine folate supplementation with or without B-complex is not recommended for CKD patients with hyperhomocysteinemia. Folic acid is not considered a useful adjuvant treatment for anemia in CKD patients without folic acid deficiency [22]. NKF KDOQI suggested folate,

TABLE 38.5 Associations between chronic kidney disease-mineral bone disease parameters and erythropoiesis-related parameters.

Vitamin D	PTH	FGF-23
↓Proinflammatory cytokines	↑Marrow fibrosis	↓Erythropoietin

FGF-23, Fibroblast growth factor-23; PTH, parathyroid hormone.

vitamin B12, and/or B-complex supplement should be prescribed to correct folate or vitamin B12 deficiency/insufficiency in CKD 1–5D and posttransplant patients based on clinical signs and symptoms (2B).

### Vitamin B12

Deficiency of vitamin B12 inhibits purine and thymidylate synthases, impairs DNA synthesis, and causes erythroblast apoptosis, resulting in anemia from ineffective erythropoiesis. Thus serum vitamin B12 level should be included in the initial evaluation of anemia in CKD. Open-label single-arm study showed that B12 supplementation in HD patients with B12 level <300 pmol/L maintained Hb level with reduced EPO requirement [144]. However, there are no randomized studies in this regard. NKF KDOQI nutrition guidelines suggested supplementing B12 only for those CKD 1–5D and postkidney transplant with vitamin B12 deficiency/insufficiency.

### Vitamin B6

Vitamin B6 is an important nutrition factor in erythropoiesis. It is a cofactor involved in the formation of aminolevulinic acid, a rate-limiting step in heme biosynthesis and it plays a role in incorporating iron into protoporphyrin, the final step in heme synthesis [145,146]. Vitamin B6 is consumed during erythropoiesis and oral B6 supplementation prevents depletion of erythrocyte B6 [146]. In dialysis patients, vitamin B6 metabolism is deranged with resulting low pyridoxal phosphate levels, a main active metabolite of vitamin B6 [147]. There is also increased vitamin B6 loss in the dialysate especially with high-flux dialysis [148]. The prevalence of B6 deficiency was estimated to be nearly 40% in dialysis patients [149,150]. However, a previous randomized trial showed that IV pyridoxine increased rather than decreased EPO resistance in HD patients [150]. There are otherwise no RCT data. Thus pyridoxine status is not included in the initial evaluation of anemia and vitamin B6 is not useful adjuvant therapy for anemia in CKD patients.

## Introduction

Humans have evolved over the last centuries when food was not always available, and such nutritional challenges created efficiency in storing excess calories and limiting energy expenditure. In 1962 Dr. Neel described a metabolic process whereby humans adapt to dynamics in caloric intake and named this evolutionary adaptation the thrifty genome [1]. As the body stores the excess intake of calories that exceed energy expenditure, insulin resistance ensues. While a thrifty genome was helpful with food scarcity, efficiency of caloric storage can be now viewed as maladaptive if food scarcity no longer exists and caloric intake is instead excessive. In this chapter, we review metabolic syndrome and its origins and the organ damage that often accompanies metabolic syndrome, including chronic kidney disease (CKD). In this chapter, you will learn the cellular consequences of insulin resistance and postulated mechanisms that mediate kidney disease in the setting of metabolic syndrome.

## Metabolic syndrome and its origins

Metabolic syndrome is a nutritional disorder rooted in the overconsumption of calories that exceeds energy expenditure leading to overweight and obesity. Obesity, defined as a body mass index (BMI) greater than or equal to 30 kg/m<sup>2</sup>, continues to be a growing epidemic within the United States and globally. Over 93 million United States adults are now obese but the prevalence differs by age and racial/ethnicity. Within age-groups the highest prevalence is among men (40.8%) and women (44.7%) age 40–59 years old and

lowest among men (34.8%) and women (36.5%) age 20–39 years [2]. Across racial/ethnic groups, obesity prevalence ranges from as low as 10.1% and 14.8% among Asian men and women, respectively, to as high as 43.1% and 50.6% among Hispanic men and women, respectively. Across the globe, obesity affects approximately 650 million people while over 1.3 billion adults are overweight, defined as a BMI between 25 and 29.9 kg/m<sup>2</sup> [3]. These statistics are based on BMI and can be misleading. Metabolic syndrome can occur with increased visceral adiposity known as android obesity that itself increases cardiovascular disease (CVD) and diabetes risk. Many argue that waist circumference or waist-to-hip ratio should be used to define obesity instead of BMI because of the importance of visceral adiposity. In addition, due to racial/ethnic differences in body size, racial/ethnic-specific definitions for both BMI and waist circumference have also been suggested.

The epidemic of obesity around the globe has been fueled by a ubiquity of calorically dense, highly palatable processed foods but not everyone has been affected. Differences in obesity risk have been attributed to numerous genetic variants across the genome, but these discovered variants each contribute very small effects on energy intake or energy expenditure. Thus the overwhelming majority of obesity is considered polygenetic [4] and a complex disease meaning that obesity occurs due to the interaction of multiple genetic factors that determines susceptibility to obesity combined with an obesogenic environment (access to densely caloric foods and sedentary lifestyle). Rarely, obesity is attributed to a single genetic variant (monogenic obesity) or to several defined genetic variants/defects or chromosomal abnormalities; these obesity

cases are usually accompanied by developmental abnormalities and termed syndromic obesity.

Regardless of genetic background, weight gain will not occur without energy intake exceeding energy expenditure. Weight gain is essential for development of metabolic syndrome but it is not sufficient because where the excess calories are stored is just as important as the weight gain itself. In contrast to overall obesity risk that is mainly mediated by nongenetic factors, the distribution patterns of adiposity are strongly familial, and genetically determined as demonstrated by strong sex differences in adiposity distribution. In some persons the excess adipose tissue may be readily stored in hips, thighs, and buttocks (peripheral), while in others the adipose tissue is mainly stored in the abdomen, liver, and muscles (truncal). Over 80% of body fat is normally stored in the subcutaneous adipose tissues while the other 20% is stored in visceral adipose tissue (omentum, mesentery, etc.) [5]. In some individuals, excess caloric intake is stored as fat preferentially in visceral adipose tissue and this is largely determined by genetic factors. These genetic factors that influence body fat distribution also account for sex differences in body fat distribution [6]. This adipose tissue stored in the abdomen or visceral adipose tissue leading to android obesity primarily drives the development of metabolic syndrome, or the clustering of major cardiovascular risk factors, including hypertension, dyslipidemia, and glucose intolerance.

In addition to where the fat is distributed, the overall ability to store excess fat also varies across individuals. The ability to store excess calories as defined by the total number of adipose cells is also largely genetic but can be influenced during childhood via being overweight. The number of adipose cells increases during childhood but then, after adolescence, remains constant during adulthood [7]. Thus regardless of weight loss or weight gain, the total number of adipose cells generally stays the same during the adult life span of an individual. Adipose cells do demonstrate cell turnover at a rate of 10% annually, but this turnover does not differ by obesity status and does not alter the total number of adipose cells available for storage [7]. When storage capacity of existing adipocytes is exceeded, fat must then be stored in the liver and muscle. Thus metabolic syndrome can be viewed as the immersion of a genetically susceptible individual combined with excess caloric intake.

### **Metabolic syndrome and its definition**

In 1988 the presence of several metabolic traits was noted to associate with a heightened risk of type 2 diabetes and CVD. This clustering of elevated glucose levels, hyperinsulinemia, high levels of very-low-density

lipoprotein triglycerides, and low-high-density lipoprotein cholesterol was entitled Syndrome X by Dr. Reaven [8] and then later changed to Metabolic Syndrome [9,10]. Increased waist circumference was later added as an additional metabolic syndrome trait by Norman Kaplan [11]. The Third Report of the Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III, or ATP III) from the National Cholesterol Education Program (NCEP) later established a definition for metabolic syndrome. The presence of at least three of the following five criteria defined metabolic syndrome: central obesity (waist circumference in men >102 cm and in women >88 cm), hypertriglyceridemia ( $\geq 150$  mg/dL), low-high-density lipoprotein (HDL) cholesterol (men <40 mg/dL, women, <50 mg/dL), elevated fasting glucose ( $\geq 110$  mg/dL), and elevated blood pressure (BP) ( $\geq 130/85$  mmHg) (see Table 39.1) [12]. The World Health Organization (WHO) also developed a definition of metabolic syndrome that tied factors associated with insulin resistance such as obesity, dyslipidemia, and hypertension. The WHO definition also allowed persons with diabetes to be diagnosed with metabolic syndrome but the diagnostic criteria could not be readily applied in clinical settings. The European Group for Study of Insulin Resistance postulated that insulin resistance was central to metabolic syndrome and used elevated fasting insulin (<75th percentile) to define insulin resistance but this meant persons with diabetes could not be diagnosed. The European group also eliminated increased urine albumin excretion as a metabolic syndrome trait given its lack of specificity with insulin resistance [13].

The use of hyperinsulinemia to define metabolic syndrome is troublesome because of heterogeneity in measurement, differing classification schemes, and lack of standardization across studies [9]. Many studies define hyperinsulinemia as insulin levels greater than the 75th percentile for the general population but this particular definition can be misleading because this assumes a threshold dependence for insulin resistance. Similar to BP, it is likely that insulin resistance is a continuous measure where even low levels of insulin resistance can lead to endothelial dysfunction and organ dysfunction in susceptible individuals. In addition, levels of insulin that indicate resistance likely vary substantially across individuals just as the association of obesity measures with insulin resistance varies across individuals. Subsequently, the NCEP and the scientific statement from the American Heart Association and the National Heart, Lung, and Blood Institute [9] eliminated insulin resistance or obesity as a required trait (Table 39.1). Instead, at least three of five potential criteria need to be present to

TABLE 39.1 Metabolic syndrome definitions.

	Insulin resistance	Elevated glucose	Low HDL	Elevated triglycerides	Overweight	Elevated blood pressure	Urine albumin excretion
<sup>12</sup> NCEP-3 + traits	Not required, not a trait	≥ 100 mg/dL	<40 mg/dL (men), <50 mg/dL (women) or medication use	≥ 150 mg/dL or medication use	WC >102 cm (men), >88 cm (women)	≥ 130/85 mmHg or medication use	Not a trait
<sup>122</sup> WHO-2 + traits	Required: top 25th percentile in insulin levels or fasting glucose ≥ 110 mg/dL or 2 h glucose ≥ 140 mg/dL	See insulin resistance	<35 mg/dL (men); <40 mg/dL (women)	≥ 150 mg/dL	WHR >0.9 (men), >0.85 (women), or BMI ≥ 30 kg/m <sup>2</sup>	≥ 140/90 mmHg	> 20 µg/min
<sup>123</sup> EGIR-2 + traits	Required: op 25th percentile in insulin levels	≥ 110 mg/dL	<40 mg/dL	≥ 180 mg/dL	WC ≥ 94 cm (men), ≥ 80 cm (women)	≥ 140/90 mmHg	Not a trait
<sup>124</sup> IDF-2 or more traits	Not required	≥ 100 mg/dL	<40 mg/dL (men); <50 mg/dL	≥ 150 mg/dL or on medications	Required: + WC ≥ 94 cm (men), ≥ 80 cm (women)	≥ 135/85 mmHg or medication use	Not a trait
<sup>125</sup> AACE	Not required	≥ 110 mg/dL; 2 h glucose ≥ 140 mg/dL	<40 mg/dL (men), <50 mg/dL (women) or medication use	≥ 150 mg/dL	Required: BMI >25 kg/m <sup>2</sup> or WC ≥ 102 cm (men), ≥ 88 cm (women)	≥ 130/85 mmHg or medication use	Not a trait

diagnose presence of metabolic syndrome. In contrast, the International Diabetes Foundation required the presence of obesity but not insulin resistance. The main problem with this strategy is that many adults with obesity do not have metabolic syndrome, especially those who are physically active [14]. Currently applied definitions do not account for family history of diabetes or CVD and do not address the organ manifestations of metabolic syndrome such as fatty liver disease and CKD factors associated with obesity and heightened mortality. It should be noted that the constellation of cardiovascular risk factors in adults with obesity was first recorded by a Swedish physician Eskil Kylin in 1923 and was conceptualized to describe [15] the end-organ damage from insulin resistance [15]. This early definition of metabolic syndrome included hyperuricemia, a trait that often predates the development of type 2 diabetes [16] and frequently accompanies CKD.

In 2009 a joint statement from the International Diabetes Federation Task Force on Epidemiology and Prevention and the National Heart, Lung, and Blood Institute along with several other organizations convened a conference to discuss the controversies regarding the terminology and criteria for metabolic syndrome diagnosis [17]. The members of all organizations agreed that metabolic syndrome represents the presence of multiple metabolic risk factors for both CVD and diabetes. However, the impact of obesity on overall health is not limited to the five metabolic syndrome traits defined by the NCEP [12]. Low HDL,

glucose intolerance, increased triglycerides, abdominal adiposity, and elevated BP are traits that heighten CVD risk [9]. Metabolic syndrome also portends heightened risk for diabetes and in most individuals reflects insulin resistance. However, the constellation of metabolic syndrome traits is not always a reflection of insulin resistance and could instead reflect dietary patterns, sedentary lifestyle, aging, imbalance in estrogen and testosterone levels and genetic factors [9]. The ATP III metabolic syndrome definition is highly specific for insulin resistance but its sensitivity for hyperinsulinemia is overall low [18–20] because criteria do not address racial, sex, or age differences in the effects of adiposity on health and the strong genetic determinants of adiposity distribution and susceptibility to metabolic syndrome [21]. In addition, metabolic syndrome itself does not impart a higher predictive value for CVD risk compared to the sum of its individual components and thus the overall value of the metabolic syndrome definition remains questionable [22–24]. Regardless of the controversy, the metabolic syndrome may be viewed as a signal of high risk for diabetes, CVD and CKD, and signals a need for implementing nutritional and exercise strategies to reduce risk.

### Metabolic syndrome and comorbidities

Based on the ATP III criteria, the overall prevalence of metabolic syndrome is now approximately 34% for both men and women [25]. The burden of metabolic syndrome is particularly high among Hispanic/Latino

adults. In the Hispanic Community Health Study/Study of Latinos, a cohort study of 16,415 Hispanics from 6 Hispanic/Latino backgrounds, metabolic syndrome was present in over one-third of men and women and increased with age. The highest prevalence of metabolic syndrome was noted among the participants with a Puerto Rican Hispanic/Latino background at 41% [26].

Lifestyle modifications affect all metabolic syndrome risk factors; this supports the hypothesis that the risk factors are not independent of each other and are all mediated by one shared factor likely insulin resistance [9,27]. Insulin resistance combined with adiposity leads to abnormal lipid accumulation in skeletal muscle and the liver. In persons without enough adipose cells, excess calories must be stored elsewhere and this may include the liver. Despite the growth of fatty liver disease termed nonalcoholic fatty liver disease (NAFLD), metabolic syndrome criteria do not include fatty liver infiltration in the absence of heavy alcohol ingestion or NAFLD [12]. NAFLD describes a wide spectrum of disease ranging from fatty infiltration (nonalcoholic steatosis) to nonalcoholic steatohepatitis to cirrhosis and liver failure. While the amount of visceral adipose tissue correlates with the amount of hepatic adiposity, abdominal adiposity itself does not itself predict risk of NAFLD [28]. It appears that both adiposity and insulin resistance are necessary for the development of NAFLD because genetic mutations of insulin receptors that alter insulin resistance can prevent hepatic adiposity [29,30]. While adiposity is not necessary for NAFLD, 90% of NAFLD is associated with insulin resistance [28]. In healthy states the liver contains only 5% lipids in total weight but as the deposition of fat increases, the fatty hepatocyte starts to resemble brown adipose tissue [28]. Thus if excess caloric storage exceeds the capacity of the set number of adipocytes available, the liver acts as an additional storage depot for lipids similar to adipose tissue. In its early stages, NAFLD may be treated thru weight loss [31–33]. However, weight loss must be at least 5% of baseline weight to achieve improvements in liver histology. In one study, participants who lost at least 7% of baseline weight showed improved liver histology and significant improvements in steatosis despite the advanced state of liver disease [32].

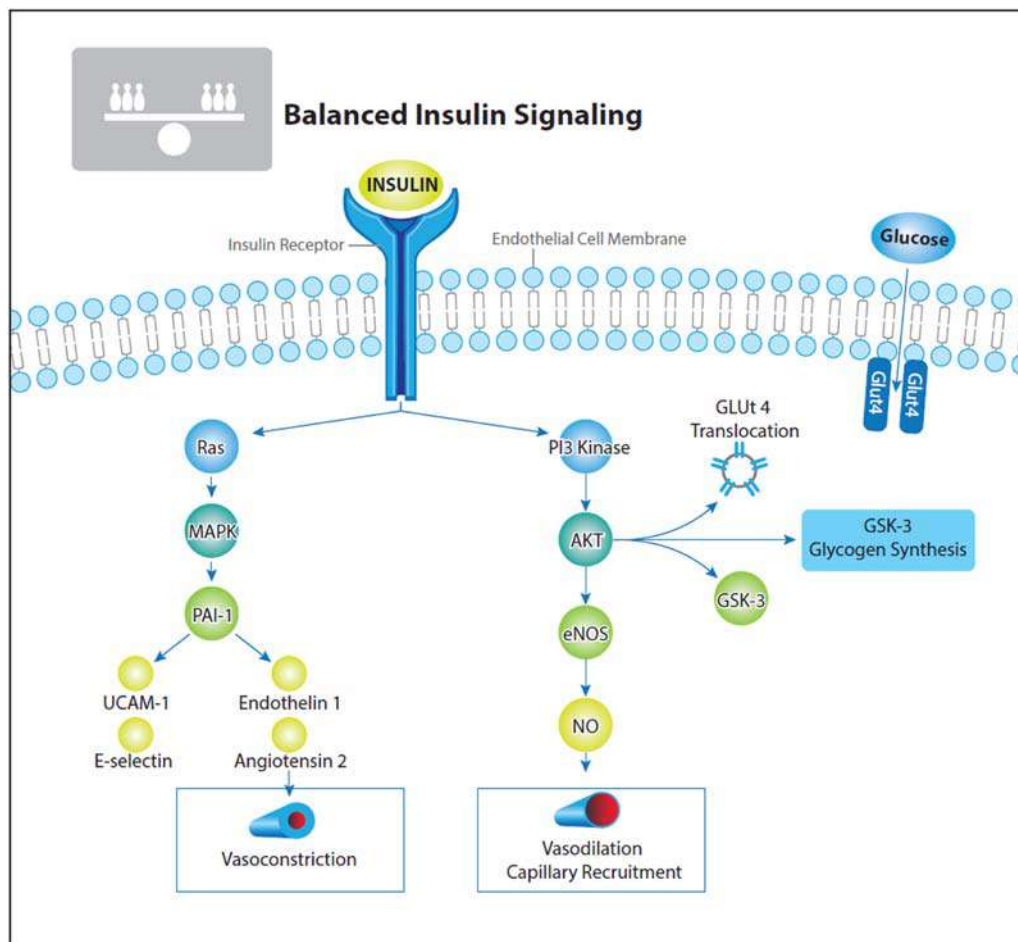

Another storage depot for excess calorie storage is muscle. Intramyocellular lipid content is high among highly trained athletes because these fatty acids provide a quick energy source for physical activity [30]. High muscle lipid content in highly active individuals does not reflect insulin resistance. Among sedentary individuals, however, the intramyocellular lipid content correlates strongly with insulin resistance and exceeds the correlation of visceral fat content with insulin resistance [30,34]. Due to the confounding

effects of exercise and the difficulties in accurate measurements, intramyocellular lipid content has not been utilized to quantify disease risk outside of research settings [30].

### Chronic kidney disease

Metabolic syndrome is associated with increased risk of CKD defined by increased urine albumin excretion [35,36]. In healthy states, albumin normally accounts for less than 10% of the total urinary protein excretion and usually ranges from 2 to 10 mg/g of creatinine (10 mg/g) excreted [37]. Levels of urine albumin excretion exceeding this threshold of 10 mg/g are associated with increased risk of CVD, end-stage kidney disease, and mortality [38]. Increased urine albumin excretion is also hypothesized to reflect endothelial dysfunction, a central feature in metabolic syndrome. To understand the ties between insulin resistance, endothelial dysfunction, and increased urine albumin excretion, it is important to remember the key roles of insulin at the cellular level as shown in Fig. 39.1.

Fig. 39.1 demonstrates the normal function of insulin, the insulin receptor, and its effects on an endothelial cell. As shown in Fig. 39.1, insulin binds to an insulin receptor on the cell membrane. The insulin receptor is a transmembrane receptor that includes two extracellular alpha subunits and two transmembrane beta subunits linked by sulfide bonds [39]. Binding of insulin to the alpha subunits of the insulin receptor induces a conformational change that turns on kinase activity in beta subunits. This then leads to phosphorylation of the beta subunits on tyrosine residues and further activation of the intracellular tyrosine kinase domain. This phosphorylation is critically important for initiating the actions of the insulin itself [40]. Tyrosine phosphorylation of an insulin receptor via binding with insulin activates phosphoinositide 3-kinase (PI3 kinase) that leads to phosphorylation of phosphatidylinositol 4,5 bisphosphate (PIP2) to yield phosphatidylinositol 3,4,5-triphosphate or PIP3. PIP3 is important for recruitment and activation of protein kinase B known as Akt, a serine, threonine kinase that regulates multiple cellular functions. Once Akt is activated via phosphorylation via the mammalian target of rapamycin complex 2, it recruits and stimulates several messengers to yield the main actions of insulin within the cell. For example, Akt leads to insertion of Glut4 transporters into the cell membrane wall—allowing glucose to enter the muscle cell [41]. Akt also phosphorylates and inactivates glycogen synthase kinase 3 that stimulates synthesis of glycogen from glucose and inhibits glycogeneolysis [42]. Activation of the mammalian target of rapamycin complex 1 by Akt leads to phosphorylation and inhibition of proteins kinases that

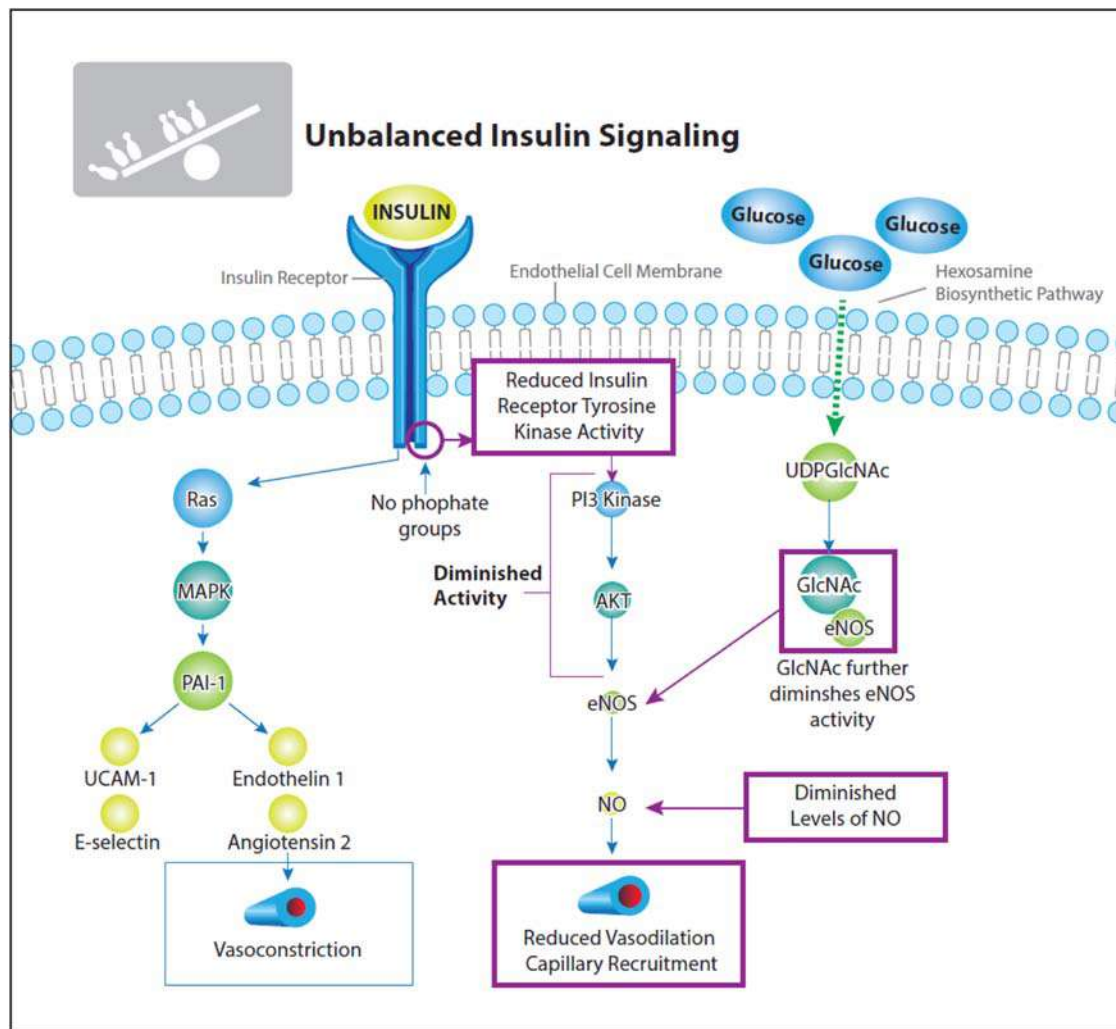

**FIGURE 39.1** Figure depicts balanced insulin signaling in a healthy state. Insulin binds to insulin receptor and leads to activation of several G protein kinases and activation of both MAPK and AKT. MAPK activation leads to upregulation of vasoconstrictor production, for example, UCAM-1, endothelin-1, and angiotensin-2. Simultaneously, AKT activation leads to upregulation of endothelial nitric oxide synthase activity, increasing NO production. *AKT*, Protein kinase B; *eNOS*, endothelial nitric oxide synthase; *GSK-3*, glycogen synthase 3 kinase; *GLUT4*, glucose transporter type 4; *MAPK*, mitogen-activated protein kinase; *NO*, nitric oxide; *PAI-1*, plasminogen activator inhibitor-1; *PI3* kinase, phosphoinositide 3-kinase; *UCAM-1*, intracellular adhesion molecule-1.

regulate expression of genes controlling protein synthesis and cell growth [39]. The phosphorylation and translocation from nucleus to cytoplasm of the transcription factors of the Forkhead Box O1 (FOXO1) by Akt blocks FOXO1 transcriptional activity. FOXO1 accelerates autophagy in response to cellular stress.

Thus the actions of insulin are not singularly focused on glucose transport but rather multiplex. Insulin is important for capillary recruitment and vasodilation to enhance cellular uptake of glucose and this occurs via the actions of endothelial nitric oxide synthase (eNOS). Activated Akt phosphorylates and activates eNOS. This is balanced by the actions of insulin on mitogen-activated protein (MAP) kinase. The activation of MAP kinase by tyrosine phosphorylation leads to upregulation of endothelin 1 production and expression of vascular cell adhesion molecule VCAM-1 and E-selectin-inducing more leukocyte endothelial interactions, endothelial cell growth,

and vasoconstriction. In healthy states, mediators of vasoconstriction and cellular proliferation are balanced with mediators of vasodilation and inhibitors of cellular proliferation (Fig. 39.1). In the setting of insulin resistance, the MAP kinase arm is not affected and can even be upregulated. In contrast, the PI3-Akt pathway is downregulated that leads to lower eNOS activation and less production of NO, a vasodilator (Fig. 39.2). In addition, the lack of cellular glucose uptake via Glut4 means that more glucose can enter the hexosamine biosynthetic pathway that normally metabolizes less than 3% of all glucose. The major end product of this pathway is uridine diphosphate N-acetylglucosamine (UDP-GlcNAc) and elevated levels of this can lead to modification of eNOS with O-GlcNAc known as O-GlcNAcylation [43] that inactivates eNOS leading to reduced levels of NO. Elevated levels of UDP-GlcNAc have been implicated in initiating and sustaining insulin resistance but this remains controversial.

**FIGURE 39.2** Unbalanced insulin signaling in an insulin-resistant state. Insulin binds to insulin receptor but due to resistance, G protein kinases are less active. MAPK is not affected but AKT is not less phosphorylated and less active leading to lower GLUT4 translocation to cell membrane and less glucose entering the cell. This leads to more glucose entering the hexosamine biosynthetic pathway. The major endproduct of hexosamine biosynthetic pathway is UDP-GlcNAc that modifies eNOS making it less active. Activation of AKT is also important for activating eNOS. The end result is less NO while vasoconstrictor production is not affected. AKT, Protein kinase B; eNOS, endothelial nitric oxide synthase; GlcNAc, N-acetylglucosamine; GLUT4, glucose transporter type 4; GSK-3, glycogen synthase 3 kinase; MAPK, mitogen-activated protein kinase; NO, nitric oxide; PAI-1, plasminogen activator inhibitor-1; PI3 kinase, phosphoinositide 3-kinase; UCAM-1, intracellular adhesion molecule-1; UDP-GlcNAc, uridine diphosphate N-acetylglucosamine.

The imbalance between vasoconstrictors (endothelin) versus vasodilators (NO) creates a vicious cycle because the vasoconstriction inhibits glucose uptake due to lower capillary recruitment and decreased local blood flow that is normally mediated via the actions of insulin [44,45]. To interrupt this cycle, eNOS activity needs to be upregulated; eNOS phosphorylation by Akt kinase can be heightened with statin medications and by adiponectin and via interruption of insulin resistance via reduction in caloric intake and weight loss (Table 39.2). Thus insulin resistance is marked by an imbalance of vasoconstrictors, vascular cell adhesion, and proliferation versus vasodilators. This leads to endothelial dysfunction in endothelial cells.

The actions of insulin resistance can also be seen within podocytes that also have insulin receptors. High extracellular glucose can induce podocyte apoptosis and both insulin resistance and glucose toxicity on podocyte function and autophagy have been implicated in the etiology of diabetic nephropathy [46,47]. Cross-sectional studies have demonstrated an association between increased urine albumin excretion and visceral adiposity, especially in adults with type 2 diabetes [48–50]. However, this association between visceral adiposity and increased urine albumin excretion may be due to the effects of elevated BP alone, and not a result of metabolic syndrome per se [51,52].

TABLE 39.2 Factors that influence endothelial nitric oxide synthase (eNOS) phosphorylation by Akt activity.

Factor	Mechanism
Weight loss/Caloric restriction	Interrupts insulin resistance via reducing glucose entering hexosamine biosynthetic pathway and reducing production of uridine diphosphate N-acetylglucosamine, an inhibitor of eNOS and via upregulation of adiponectin production
Adiponectin	Adiponectin phosphorylates eNOS at Ser <sup>1177</sup> and activates AMP-activated protein kinase
Statin medications	Blocks formation of many compounds, such as farnesylpyrophosphate and geranylgeranyl pyrophosphate, nonsteroidal isoprenoid compounds, that inactivate G-proteins important for upregulating eNOS activity

The link between obesity and kidney disease is not limited to increased urine albumin excretion. Obesity, especially morbid obesity, strongly impacts risk of all stages of CKD. Obesity, especially morbid obesity, appears to be a very strong risk factor for future risk of end-stage renal disease but this association appears strongest if obesity occurs during the early years of adulthood. One of the largest cohort studies in the United States examined 320, 252 adults who were age 18–34 years when they participated in a health screening exam during years 1964 and 1985. After 15–34 years of follow-up, morbid obesity ( $\text{BMI} \geq 40 \text{ kg/m}^2$ ) was associated with a sixfold higher risk of kidney failure compared to an ideal BMI ( $18.5\text{--}24.9 \text{ kg/m}^2$ ) [53]. A cohort that followed adolescents thru adulthood also found similar associations of morbid obesity with kidney failure [54]. In contrast, obesity occurring later in life has not demonstrated strong associations between obesity and kidney failure risk [55–57]. The age modification of kidney disease risk associated with obesity may be due to cumulative exposure to high insulin and glucose levels if obesity begins at an early age. This hypothesis is supported by studies showing that associations of obesity with kidney failure risk is limited to individuals with metabolic syndrome and/or elevated BP [55,58]. In the REasons for Geographic and Racial Differences in Stroke (REGARDS) study, metabolic syndrome was a strong modifier of the association of obesity with kidney disease. Among 21,840 REGARDS participants with a mean baseline age of 65 years and followed for  $6.3 \pm 1.3$  years, 247 developed kidney failure. Obesity defined by a  $\text{BMI} \geq 30 \text{ kg/m}^2$  was associated with a twofold higher risk for kidney failure compared to an ideal BMI of  $18.5\text{--}24.9 \text{ kg/m}^2$  after adjustment for covariates. However, this association of higher kidney failure risk with obesity status was only noted in the REGARDS participants with metabolic syndrome [55]. Similar findings were also noted in a large cohort of adults followed for risk of incident CKD [59]. Measures of obesity were not associated with incident CKD in the absence of metabolic syndrome traits.

Measures of abdominal obesity such as increased waist circumference or waist-to-hip ratio are more consistently associated with kidney disease risk compared to BMI [56,60,61]. In addition, multiple studies have consistently demonstrated an association of abdominal obesity and increased urine protein (mainly albumin) excretion in several types of populations [48,49,62]. Differences in kidney disease risk across obesity measures are likely due to the fact that waist circumference and waist-to-hip ratio reflect visceral fat, a strong risk factor for development of insulin resistance, while BMI includes visceral fat and lower body fat. Even with these visceral adiposity measures, obesity among older adults (e.g., 60 years and older) only modestly increases the risk of kidney failure and associations appear largely driven by hypertension and diabetes. In contrast, if obesity, especially morbid obesity, initiates during adolescence or young adulthood then the individual is exposed to metabolic syndrome traits for a prolonged period of time, heightening kidney disease risk.

Metabolic syndrome defined by the NCEP ATP III criteria is associated with moderately increased odds of both incident and prevalent CKD [63–65]. Odds of CKD defined as an estimated glomerular filtration rate (eGFR)  $< 60 \text{ mL/min/m}^2$  or a spot urine albumin/creatinine ratio ( $30\text{--}300 \text{ mg/g}$ ) increased linearly with the number of metabolic syndrome traits from 2.21 [95% confidence interval (CI), 1.16–4.24] with 2 traits to 5.85 (95% CI, 3.11–11.0) with 5 traits compared to individuals with no traits. In a cross-sectional analysis of a population-based survey of the US population [64], similar findings were noted in the Jackson Heart Study, a cohort of African American adults. Among the Jackson Heart cohort, elevated BP, triglycerides, fasting blood glucose, and abdominal obesity were all significantly associated with increased odds of CKD [66]. However, the presence of metabolic syndrome was associated with a 2.2-fold increased odds of CKD (95% CI, 1.78–2.78). Among persons with established CKD such as the African-American Study of Hypertension and Kidney Disease, in which all trial participants had CKD at baseline, the

presence of metabolic syndrome was associated with higher levels of urine protein excretion at baseline but not with CKD progression [67]. In the Strong Heart Study a cohort of American Indian adults demonstrated that the presence of metabolic syndrome was associated with heightened risk of incident CKD but this association was largely driven by development of diabetes and hypertension [68]. Most studies find moderate associations of metabolic syndrome with incident CKD. A meta-analysis published in 2011 found eleven studies with a total of 30,146 adults followed over time for CKD defined as an eGFR < 60 mL/min/1.73 m<sup>2</sup>. The presence of metabolic syndrome was associated with a 1.6-fold increased odds of CKD (95% CI, 1.3, 1.8) and the higher the number of metabolic syndrome traits present, the stronger the association (trend *P* value = .02). The strongest association with CKD for a given metabolic syndrome trait was noted for elevated BP with an odds ratio (OR) of 1.6 (95% CI 1.3, 2.0) and lowest for abdominal obesity (OR 1.2; 95% CI 1.1, 1.3), and impaired fasting glucose (OR 1.1; 95% CI 1.0, 1.3). The metaanalysis also reported that three studies showed that metabolic syndrome was associated with an increased risk for development of increased urine albumin excretion [69].

Information on the link between metabolic syndrome and CKD risk remains fairly limited because most cases of kidney disease evolve over decades and not within a few years so cohort studies need extended follow up to fully evaluate potential risk factors. The metabolic syndrome trait most consistently and strongly associated with loss of eGFR over time in cohort studies is elevated BP. The Atherosclerosis Risk in Communities Study with 30 years of follow-up has demonstrated that the presence of hypertension is associated with a faster rate of eGFR decline and higher risk of CKD even after adjustment for diabetes status [70]. We also know that higher BP among adults with diabetes is associated with a higher risk of decreased GFR, especially in the presence of increased urine albumin excretion [71,72]. Based on metaanalyses of well-designed clinical trials, a systolic BP (SBP) target <130 mmHg is now recommended for individuals with nondialysis dependent CKD [73,74]. The evidence supporting this BP target is strongest for persons without diabetes mellitus [75] or persons with moderate to severely increased urine albumin excretion [72,73]. Among individuals with diabetes, intensive glucose control lowers risk of developing increased urine albumin excretion, especially during the early stages of diabetes. The Action to Control Cardiovascular Risk [76] in Diabetes study showed small but significant reductions in the absolute risk of developing increased urine albumin excretion with intensive glucose lowering. A metaanalysis of intensive glucose control studies in type 2 diabetes mellitus (T2DM) 1 [77] with 28,065

adults with type 2 diabetes followed for 2–15 years showed significantly reduced risk of both moderately increased [relative risk (RR) = 0.86, 95% CI: 0.76–0.96] and severely increased urine albumin excretion (RR = 0.74, 95% CI: 0.65–0.85) with intensive glucose control [median hemoglobin A1c (HbA1c) 6.4%–7.4%]. To date, intensive glucose control has not been associated with reduced risk of kidney failure although data suggest trends toward benefits with intensive control [78]. Several studies have also shown that even among adults without established diabetes, higher HbA1c values are associated with faster rate of age-associated decline in the eGFR [79,80]. In a secondary analysis of the Outcome Reduction with Initial Glargine Intervention trial that included 12,537 people with T2DM or prediabetes followed for 6.2 years, RR of kidney failure was 54% higher (95% CI; 24%, 91%) for every 1% higher baseline HbA1c values among trial participants. In addition, long-term glucose control with pancreas transplant had demonstrated reversibility of diabetic nephropathy posttransplant [81], but this was only seen histologically after 10 years of normal glucose levels [82].

Higher urine albumin or protein excretion is associated with faster GFR decline in the setting of kidney disease [83–85]. While BP-lowering will lower urine protein excretion [71,86], caloric restriction and weight loss are also effective interventions regardless of BP because weight loss improves insulin resistance via downregulation of fatty acid mobilization [87] and reductions in inflammation and renin–angiotensin–aldosterone system activation [88]. High concentration of circulating free fatty acids (FFAs) promotes insulin resistance by competitively inhibiting glucose uptake by muscle. For example, urine protein excretion decreases rapidly after bariatric surgery among morbidly obese adults likely because caloric intake during the first 6 months is markedly reduced [89]. Declines in urine protein excretion occur as early as 1 month with caloric restriction. A metaanalysis of 13 studies of weight-loss interventions, including dietary restriction, exercise, antiobesity medications, and surgery with a total of 522 participants [90] showed that urine protein or albumin excretion decreased significantly with weight loss, regardless of the intervention. On average, urine protein excretion decreased by 110 mg (95% CI, 60–160 mg, *P* < .001) and urine albumin excretion decreased by 1.1 mg (95% CI, 0.5–2.4 mg, *P* = .011) per kilogram of weight loss, for both surgical and medical interventions.

One cellular metabolic pathway that elucidates mechanisms whereby caloric restriction reduces protein excretion is upregulation of adiponectin that improves insulin sensitivity at the cellular level. Adiponectin receptors reside on podocytes and may improve function and survival [91,92]. Adiponectin

expression is upregulated via the Sirt1-Foxo1 pathway [93]. Sirt1, an NAD<sup>+</sup>-dependent deacetylase, expressed in the renal inner medulla, activates the cell cycle protein Foxo1 [93,94], which then forms a transcriptional complex with C/EBP $\alpha$  at the adiponectin gene promoter site and turns on gene expression. Adiponectin can upregulate eNOS activity via phosphorylation of eNOS at Serine residue 1177 similar to actions of Akt previously described [95]. Increased activity of eNOS leads to higher NO levels and increased blood flow and vasodilation and can reduce BP.

### Treatment of metabolic syndrome

Because metabolic syndrome confers such a strong risk for cardiovascular and kidney diseases and future development of type 2 diabetes, the syndrome should be addressed with a diet and lifestyle intervention. The best evidence we have for amelioration of metabolic syndrome with a lifestyle intervention is from the Diabetes Prevention Program (DPP). The DPP [96] randomized persons at high risk for type 2 diabetes to either an intensive lifestyle intervention, metformin, or a placebo. After 3 years, persons in the intensive lifestyle intervention had a 58% lower risk of developing type 2 diabetes compared to the placebo group. The annual risk of developing type 2 diabetes was 5% in the lifestyle intervention group and 11% in the placebo group. The benefits of lifestyle changes were most prominent among persons age 60 years and older in whom risk of developing type 2 diabetes was reduced by 71% compared to placebo. Metformin use was also associated with reduced risk of developing type 2 diabetes compared to placebo. Risk of developing type 2 diabetes was 31% lower compared to placebo and effects were strongest among women with a history of gestational diabetes and among those with a baseline BMI of 35 kg/m<sup>2</sup> and higher. After the trial ended, participants were then followed for the development of type 2 diabetes. After 15 years of follow-up, 55% and 56% of participants assigned to the lifestyle intervention and metformin, respectively, developed type 2 diabetes compared to 62% of participants assigned to placebo during the trial [97]. Similar findings have been shown in similar trials completed outside the United States in which diet and lifestyle changes led to approximately 30%–40% lower risk of type 2 diabetes over 10–20 years [98,99].

Lifestyle interventions for metabolic syndrome must include both weight loss and physical activity. In the DPP trial, weight loss goals were 7% or higher of baseline weight and physical activity goals were set at 150 minutes of vigorous activity such as brisk walking to expend approximately 700 kcal/week. Weight loss

recommendations were 1–2 lbs/week with reducing between 500 and 1000 cal/day depending on the baseline body weight.

The type of diet may also help reduce risk of type 2 diabetes as implementation of a Mediterranean diet high in monosaturated fats such as olive oil and low in saturated fats has been shown to reduce risk of type 2 diabetes and kidney disease [100]. In addition, observational studies suggest that persons with high adherence to a Mediterranean diet have a lower risk of developing metabolic syndrome [101]. The Western diet is high in processed foods, sugar, and fat and these factors all increase risk of developing metabolic syndrome and T2DM.

Metformin was approved for the prevention of type 2 diabetes by the FDA in 2017 and is recommended by the American Diabetes Association for diabetes prevention in high-risk individuals [102]. Metformin is a biguanide that inhibits hepatic glucose output. However, only 50% of the drug is absorbed and reaches the liver while the other 50% accumulates in the gut. Within the gut, metformin alters the microbiome by increasing longevity of gut bacteria that consume calories within the intestine [103].

Other medications that may be considered for addressing metabolic syndrome and insulin resistance are the thiazolidinediones (TZDs). The TZD class of glucose-lowering medications promotes insulin sensitivity by activating the peroxisome proliferator-activated receptor-gamma that leads to upregulation of genes involved with lipid metabolism and adipogenesis. The use of this class of drugs is associated with reduction in FFAs and urine albumin excretion in adults with type 2 diabetes via amelioration of insulin sensitivity in liver, muscle, and fat tissue [104]. Trials of TZDs have not shown that this class of medications slow kidney function decline or reduce risk of incident CKD or kidney failure. The use of this medication has been impeded by its risks of sodium retention and weight gain leading to heart failure.

Another class of drugs, the glucagon-like peptide-1 (GLP-1) receptor agonists, may become increasingly more relevant for management of metabolic syndrome [105]. GLP-1, a peptide hormone, is secreted in response to circulating glucose and increases pancreatic insulin secretion and decreases glucagon secretion. Normally, GLP-1 is rapidly degraded by the enzyme dipeptidyl peptidase IV but the GLP-1 receptor agonists are resistant to degradation by this enzyme. Receptors for GLP-1 reside in multiple tissues in the body, including the hypothalamus, pancreas, and kidney. Currently, drugs in this class are approved for use in persons with type 2 diabetes but one drug, liraglutide, is approved for management of obesity by the Federal Drug Administration. These drugs bind to

receptors in the hypothalamus and increase satiety and decrease appetite. Liraglutide use is generally associated with weight loss (~6 kg) and other GLP-1 agonists can also lead to weight loss, albeit less. This drug class is also associated with an approximate 5 mmHg drop in SBP and diastolic BP and a reduction in serum triglycerides. Effects on metabolic syndrome traits are likely mediated mainly via weight loss.

While this drug class is not approved for treatment of metabolic syndrome, metabolic syndrome traits may be positively affected with GLP-1 agonists. Animal models that lack GLP-1 receptors show higher urinary albumin levels and mesangial expansion in the setting of diabetes and this is attributed to higher levels of oxidative stress due to increased glomerular superoxide. Liraglutide in animals lacking GLP-1 receptors ameliorates the effects of hyperglycemia in the kidney by suppressing superoxide production. In the Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results trial, the use of liraglutide was associated with a 22% lower risk of a primary kidney endpoint defined as the development of macroalbuminuria, doubling of serum creatinine and  $\text{eGFR} < 45 \text{ mL/min/1.73 m}^2$ , the need for renal replacement therapy, and death from renal causes (95% CI: 8%, 33%;  $P = .03$ ) compared to placebo. However, most of the renal endpoints in this trial were new-onset macroalbuminuria. The renal benefit of liraglutide was mainly derived from a 26% significant reduction in new-onset macroalbuminuria (95% CI 9%, 40%) without any significant changes in  $\text{eGFR}$ . The use of liraglutide in this trial was associated with a 2.3 kg weight loss and a drop of 1.2 mmHg in SBP. Similar findings were noted in the Trial to Evaluate Cardiovascular and other long-term outcomes with semaglutide (SUSTAIN-6) with 46% reduction (95% CI 23%, 63%;  $P < .001$ ) in risk of developing macroalbuminuria relative to placebo among adults with type 2 diabetes [106].

Another drug class with demonstrated benefits on metabolic syndrome traits is the dipeptidyl peptidase-4 inhibitors. This class of drugs increases beta cell mass and function and improves liver, muscle, and adipose tissue insulin sensitivity [107]. While fatty acid oxidation is increased with DPP-4 inhibitors, hepatic triglyceride synthase is reduced leading to lower triglyceride levels and decreased lipogenesis. These drugs also delay gastric emptying potentiating satiety leading to decreased caloric intake. A pooled analysis of 13 clinical trials of the DPP-4 inhibitor linagliptin versus placebo [108] with follow-up ranging from 12 to 76 weeks showed linagliptin reduced risk of developing a kidney endpoint defined as new-onset micro or macroalbuminuria, loss of baseline  $\text{eGFR} > 50\%$ , acute renal failure, or death from any cause. The absolute risk difference in kidney endpoints was 2.8% with lower risk in the linagliptin group (HR = 0.84; 95%

CI: 0.72–0.97,  $P = .02$ ). Currently, the DPP-4 inhibitors are only approved for treatment of type 2 diabetes.

Another class of drugs to consider for management of metabolic syndrome in certain patients is the sodium–glucose cotransporter type 2 (SGLT2) receptor inhibitors, especially for patients with a high risk of kidney failure. One of these drugs, canagliflozin, was the first diabetes drug approved by the Federal Drug Administration for the prevention of cardiovascular events. The SGLT2 receptor is found in the early proximal tubule and is responsible for mediating sodium and glucose reabsorption. When SGLT2 is inhibited, glucose and sodium are excreted in the urine. Due to the loss of sodium, which is sensed by the macula densa in the juxtaglomerular apparatus, intraglomerular pressure is reduced due to afferent arteriolar vasoconstriction. The loss of glucose leads to lower insulin levels and these effects along with sodium loss explain the diuretic effects of this drug class. The diuresis leads to weight loss and lowered BP. In the CVD safety trial of empagliflozin (EMPA-REG), use of empagliflozin in 7020 adults with type 2 diabetes and high CVD risk showed significantly lower risk of kidney outcomes defined as progression to macroalbuminuria, doubling of serum creatinine level associated with an  $\text{eGFR} < 45 \text{ mL/min/1.73 m}^2$ , initiation of renal replacement therapy and death from renal disease. Absolute risk reduction of renal endpoints with empagliflozin was 6.1%—with events occurring in 12.7% of those treated with empagliflozin and 18.8% in the placebo group ( $P < .001$ ). Similar to other trials of glucose-lowering medications, most renal endpoints were increased urine albumin excretion, and in the EMPA-REG trial, reduction in new-onset macroalbuminuria was responsible for most of the renal benefits with empagliflozin. In animal models, this drug class shows reduction in oxidative stress, inflammation, fibrosis, and tubular senescence that would provide direct kidney benefits [109]. A metaanalysis of four trials of SGLT2 inhibitors in 38,723 adults with type 2 diabetes [110], SGLT2 inhibitors reduced the risk of dialysis, transplantation, or death due to kidney disease by 33% (95% CI 14%, 48%,  $P = .0019$ ) relative to placebo. Risks of both kidney failure (RR = 0.65, 0.53–0.81,  $P < .0001$ ) and acute kidney injury (RR = 0.75, 0.66–0.85,  $P < .0001$ ) were significantly reduced with SGLT2 inhibitor use. Benefits were consistent across baseline urine albumin excretion levels and use of renin–angiotensin system inhibitors. Because these drugs do not increase insulin secretion, they may have benefits in adults without established diabetes and could reduce kidney disease risk in the setting of metabolic syndrome.

The CREDENCE Trial [111] examined canagliflozin in adults with type 2 diabetes and kidney disease, defined as an  $\text{eGFR} 30\text{--}90 \text{ mL/min/1.73 m}^2$  and

albumin-to-creatinine ratio 300–5000 mg/g and receiving treatment with a renin–angiotensin system blocker. The trial was stopped early after an interim analysis showed the risk of kidney failure and cardiovascular events was 30% (95% CI, 18%, 41%;  $P = .00001$ ) lower in the canagliflozin group than in the placebo group at a median follow-up of 2.62 years. Kidney endpoints were defined as development of kidney failure, doubling of baseline serum creatinine level, or death from renal causes. Risk of the composite renal outcome was 34% (95% CI, 18%, 47%;  $P < .001$ ) relative to placebo while risk of kidney failure was 32% lower (95% CI, 14%, 46%;  $P = .002$ ) relative to placebo. Risk of cardiovascular events defined as cardiovascular death, myocardial infarction, or stroke was reduced by 20% (95% CI, 5%, 33%;  $P = .01$ ) while hospitalization for heart failure was reduced by 39% (95% CI, 20%, 53%;  $P < .001$ ) relative to placebo. In contrast to the CREDENCE Trial, the study to evaluate the effects of dapagliflozin on renal outcomes and cardiovascular mortality in patients with CKD NCT03036150 is enrolling patients with both diabetic and nondiabetic CKD and will help determine whether this drug class shows similar benefits to adults with type 2 diabetes and may provide evidence for its use in metabolic syndrome.

Finally, the importance of lifestyle modifications, including dietary changes, cannot be overstated for those with metabolic syndrome and obesity. Diets that emphasize the consumption of whole, plant-based foods have been repeatedly linked with weight loss, likely due to the presence of fiber in plant-based foods and other differences [112]. Several observational studies have shown that increasing fiber consumption is directly associated with weight loss [113]. For example, in one study, every 1-g increase in dietary fiber intake was associated with a 0.25-kg reduction in body weight [114]. A systematic review and metaanalysis of clinical trials found that vegetarian diets were associated with a 3.4-kg weight loss in an intention-to-treat analysis, with larger weight losses being achieved in those who completed the trials [115]. Fiber's ability to facilitate weight loss is likely related to the lower caloric density of those foods and increases in satiety hormones like GLP-1 and peptide YY (both of which are increased by soluble fiber) [116].

In addition to weight loss, the consumption of plant-based foods may also have benefits for kidney-related outcomes. In the Adventist Health Study-2, researchers found that among nearly 73,000 participants followed over an average of 5.8 years, those consuming a vegetarian diet had a 52% reduced risk (95% CI, 8%, 82%) of kidney disease associated mortality [117]. Consumptions of diets emphasizing plant-based foods have also been associated with less proteinuria and a lower risk of CKD [118,119]. Benefits of plant-based foods may also occur with only partial inclusion of these foods into a diet. In a

randomized, controlled trial of the use of fruits and vegetables for metabolic acidosis secondary to CKD, Goraya et al. found reductions in BP, weight, and albuminuria along with improvements in metabolic acidosis comparable to oral bicarbonate with as little as two to four servings of fruits and vegetables per day [120]. Other benefits of a plant-based diet in kidney disease may include reductions in serum phosphate levels and uremic toxins [121].

In summary, metabolic syndrome is defined by the presence of multiple traits that occur due to caloric consumption exceeding energy expenditure. Persons with a genetic predisposition to store these excess calories in the abdomen and those with reduced fat storage capacity have increased susceptibility to develop metabolic syndrome. Metabolic syndrome is associated with increased risk of CKD. Weight loss, dietary changes, and exercise remain the cornerstone treatment for metabolic syndrome. Medications that improve insulin sensitivity or impair kidney glucose reabsorption may also help ameliorate the impact of metabolic syndrome on kidney disease risk.

# Nutritional and metabolic management of obesity and the metabolic syndrome in patients with chronic kidney disease

*Allon N. Friedman*

Department of Medicine, Indiana University School of Medicine, Indianapolis, IN, United States

## Introduction

Obesity has in recent decades emerged as a premier global health problem. In 2016 more than 1.9 billion adults worldwide were overweight, with 650 million of these being obese [1]. Individuals with or at risk for chronic kidney disease (CKD) are also adversely affected by this trend. In fact, obesity is arguably replacing uremia-related undernutrition as the main nutritional problem facing patients with CKD, at least in the United States [2]. Obesity is a wellspring not only a wellspring for many of the most common and important risk factors for CKD but is also independently associated with the development and progression of CKD. It is not an exaggeration to state that CKD in modern times is to a large degree a complication of obesity. Consequently, strategies to mitigate obesity may help in managing and treating CKD. This chapter will review the epidemiology, trends, pathophysiology, and management strategies for obesity-related kidney disease and the metabolic syndrome, focusing primarily on individuals with CKD who have not yet reached end-stage kidney disease (ESKD).

## Magnitude of the obesity crisis

Obesity is undoubtedly a scourge of modernity [1]. Though traditionally a problem limited to affluent Western societies, obesity has also become increasingly common in developing nations [3]. It is evident that obesity has greatly affected the CKD population as well. Between 2011 and 2014 the prevalence of obesity in US adults with CKD was 44.1% [2]. This represents

a 5% absolute increase in obesity compared to the preceding 12 years (and a higher prevalence than the 37.9% seen in the general populace during that period [4]). Worse, over 25% of CKD patients manifested more severe degrees of obesity.

A plausible explanation for such findings is that the growing abundance of inexpensive, calorie-dense foodstuffs combined with an increasingly sedentary lifestyle affect individuals with CKD at least as much as the general populace. The fact that CKD patients are limited in their physical activity due to physical impairments may further compound the problem. However, the precise cause of the obesity crisis is still open for debate [5].

## Defining obesity in persons with chronic kidney disease

The definition of “excess” body fat is somewhat arbitrary and lacks a validated threshold. Though a number of techniques are available to accurately measure body fat content and/or patterns of unhealthy fat deposition, such as neutron activation analysis, dual-energy X-ray absorptiometry, bioelectrical impedance, air-displacement plethysmography, and computed tomography, they are used primarily for research purposes.

In clinical practice, obesity is determined by simple measurements that “define” excess body fat in a manner that is partly derived from their association with clinical risk [6]. The most commonly used marker of obesity in patients with CKD is the body mass index (BMI), which is a ratio of weight to height [i.e., weight (kg) divided by height squared ( $m^2$ )].

TABLE 40.1 Classifying overweight and obesity according to body mass index (BMI), waist circumference, and associated disease risk.

Classification	BMI (kg/m <sup>2</sup> )	Obesity class	Disease risk <sup>a</sup> relative to normal weight and waist circumference	
			Men ≤102 cm/Women ≤88 cm	Men >102 cm/Women >88 cm
Underweight	< 18.5		—	—
Normal weight <sup>b</sup>	18.5–24.9		—	—
Overweight	25.0–29.9		Increased	High
Obesity	30.0–34.9	I	High	Very high
	35.0–39.9	II	Very High	Very High
Extreme obesity	≥ 40	III	Extremely high	Extremely high

<sup>a</sup>Disease risk for type 2 diabetes, hypertension, and cardiovascular disease.

<sup>b</sup>Increased waist circumference can increase risk even in persons of normal weight.

Adapted from National Institutes of Health: National Heart, Lung, and Blood Institute. Clinical guidelines on the identification, evaluation, and treatment of overweight and obesity in adults. Bethesda, MD: National Institutes of Health: National Heart, Lung, and Blood Institute; 1998.

Simple to calculate and easy to employ, the BMI is a reasonably good indicator of total body fat content in the general population as well as in patients with CKD [6–8]. One study of 77 patients with an estimated mean glomerular filtration rate (eGFR) of 40 mL/min/1.73 m<sup>2</sup> found that a BMI greater than 30 kg/m<sup>2</sup> had a 100% positive predictive value for detecting obesity compared with a reference body composition method, while its negative predictive value was only 30% [7]. That is, a high BMI confirmed obesity while a lower BMI did not exclude obesity. This study highlights some of the limitations of BMI, including that it cannot distinguish lean from fat mass, peripheral from central/visceral fat, or volume excess from fat excess. These limitations have spurred interest in alternative anthropometric measurements such as waist circumference and waist-to-hip ratio that can detect excess visceral fat in a manner that the BMI cannot. Visceral fat is currently considered an important causal risk factor for insulin resistance, the metabolic syndrome, and cardiovascular disease [9]. Studies suggest that these alternative metrics add additional prognostic information in the CKD population [10–12]. Table 40.1 shows the classification of overweight and obesity and associated disease risk by BMI and waist circumference.

### Clinical indicators of kidney disease in obese individuals

The two most important clinical markers of kidney function and disease are the GFR and proteinuria (or albuminuria) [13]. The GFR is most accurately measured by plasma or urinary clearance of inulin or other exogenous markers [14]. However, because direct measurement is cumbersome, time-consuming, and too costly for routine use, most clinicians and many researchers rely on creatinine-based formulas such as the Cockcroft–Gault

[15], Modification of Diet in Renal Disease [16], and CKD Epidemiology Collaboration [17,18] equations to estimate GFR. Such equations should be used with caution in individuals who are obese or whose weights are fluctuating for the following reasons: first, estimating equations work reasonably well in the populations they were derived in, but none of the equations were derived in primarily obese populations, which explains why their accuracy is reduced in that population [19–22] and in patients with fluctuating weight. Second, estimating equations rely heavily on serum creatinine as an endogenous filtration marker. Serum creatinine is generated primarily from muscle so all other things being equal the greater the muscle mass, the higher the serum creatinine. Therefore any change in muscle mass as a result of weight gain or loss will influence serum creatinine generation and make it difficult to differentiate true effects on glomerular filtration from spurious changes in serum creatinine. An alternative endogenous filtration marker in obese patients is serum cystatin C. Cystatin C is more closely associated with measured GFR than creatinine in very obese individuals [23]. However, even cystatin C may be influenced by body mass [24,25].

Third, GFR-estimating equations usually include an adjustment for body surface area to equalize differences in body size between individuals. This indexing strategy is based upon the observed relationship in mammals that GFR is proportional to body size [26] that is presumably related to the fact that the kidney modifies its excretory (e.g., filtration) capabilities based upon the amount of metabolic by-products generated by the body [27,28]. The use of body surface adjustments in obese individuals presents challenges because it is lean and not fat mass that generates most metabolic waste so adjusting for lean *and* fat mass introduces systemic bias and error [29]. Because of these pitfalls, clinical trials should ideally directly measure rather than estimate and/or index GFR for body size in individuals who are gaining or losing weight [23,30].

Proteinuria or albuminuria can be measured from a 24-hour urine collection or estimated from a spot urine protein (or albuminuria)-to-creatinine ratio. While either method is acceptable in obese individuals, the latter is susceptible to bias when used for serial measurements during weight change because urine creatinine is dependent upon muscle mass and will change with weight gain or loss. It will therefore be difficult to distinguish if a rise in the urine protein-to-creatinine ratio after weight loss represents a true increase in proteinuria or alternatively reflects a reduction in urinary creatinine. In the setting of weight change, a 24-hour urine collection is, therefore, the preferred method of measurement.

### The metabolic syndrome

The risk that obesity confers is heightened by the presence of additional risk factors like elevated blood pressure, dyslipidemia, and insulin resistance  $\pm$  glucose intolerance that are together known as “the metabolic syndrome” [31]. Originally designed to identify a set of risk factors for cardiovascular disease that cluster together, the metabolic syndrome is associated with increased risk for development of proteinuria/albuminuria [32], development and progression of CKD [33–35], and ESKD [36]. There is some disagreement as to whether obesity remains a risk factor for CKD in obese patients who do not manifest the “metabolic syndrome” phenotype and who are “metabolically healthy” [37–39].

In addition, there is an ongoing debate over the best definition and usefulness of the metabolic syndrome classification system. There are at least two definitions of the metabolic syndrome, each of which differs slightly from the other [31,40] (Table 40.2).

Moreover, the definition of metabolic syndrome has been criticized for, among other things, its ambiguous criteria and ill-defined thresholds, the uncertainty of using insulin resistance as a unifying etiology, and its questionable value in defining cardiovascular risk and in diagnosing and treating patients [41].

### Obesity and risk for chronic kidney disease

A consensus has emerged from the medical literature indicating that obesity accounts for a large proportion of CKD. Population attributable risk analyses estimate that approximately one-fifth to one-fourth of kidney disease cases could be prevented by eliminating overweight and obesity, a proportion that would invariably be much higher if the intermediate CKD risk factors diabetes and hypertension were included [42]. Another population-based study reports that the lifetime risk of CKD is 32.5%, 37.6%, and 41% in persons who are normal weight, overweight, or obese, respectively [43].

Weight gain or obesity are independent predictors for the development of proteinuria, kidney stones, acute kidney injury, and CKD in the general population [44–50] and in higher risk groups like individuals with prehypertension [51]. These observations include

TABLE 40.2 Definitions of the metabolic syndrome.

#### **ATP III definition**

Any three or more of the following criteria:

1. Waist circumference  $>102$  cm in men and  $>88$  cm in women
2. Serum triglycerides  $\geq 1.7$  mmol/L
3. Blood pressure  $\geq 130/85$  mmHg
4. HDL cholesterol  $<1.0$  mmol/L in men and  $<1.3$  mmol/L in women
5. Serum glucose  $\geq 6.1$  mmol/L ( $\geq 5.6$  mmol/L may be applicable)

#### **WHO definition**

Diabetes, IFG, IGT, or insulin resistance (assessed by clamp studies) and at least two of the following criteria:

1. Waist-to-hip ratio  $>0.90$  in men or  $>0.85$  in women
2. Serum triglycerides  $\geq 1.7$  mmol/L or HDL cholesterol  $<0.9$  mmol/L in men and  $<1.0$  mmol/L in women
3. Blood pressure  $\geq 140/90$  mmHg
4. Urinary albumin excretion rate  $>20$   $\mu\text{g}/\text{min}$  or albumin-to-creatinine ratio  $\geq 30$  mg/g

ATP, Third Report of the National Cholesterol Education Program's Adult Treatment Panel; HDL, high-density lipoprotein; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; WHO, World Health Organization.

a wide range of ethnic groups and ages. One such study of a global database that included over 5.4 million healthy individuals found the risk of a decline in the GFR progressively and independently increased as the BMI rose above 25 kg/m<sup>2</sup> [52]. A high BMI has also been linked to progression of preexisting glomerulonephritis (i.e., IgA nephropathy) and inherited illnesses like polycystic kidney disease and nondiabetic kidney disease [53–55].

Obesity is also a risk factor for progression to ESKD. In a population of over 300,000 adults, a higher BMI independently predicted the development of ESKD even after adjusting for baseline blood pressure, the presence of diabetes, and other risk factors [56]. Compared to individuals with normal BMI the adjusted relative risk for ESKD was 1.87 for overweight individuals, 3.57 for a BMI of 30–34.9 kg/m<sup>2</sup>, 6.12 for a BMI of 35–39.9 kg/m<sup>2</sup>, and 7.07 for a BMI ≥ 40 kg/m<sup>2</sup>. This relationship holds in younger individuals as well. A retrospective study of 1.2 million Israeli adolescents followed over an average of 25 years reported that being overweight or obesity independently associated with the development of ESKD. The relationship was notably pronounced for diabetic ESKD, with a hazard ratio of ~39 for youths in the >95th BMI percentiles [57]. Obesity has even been linked to a more rapid decline in residual kidney function at time of initiation of dialysis [58] and a family history of end-stage renal disease (ESRD) [59]. Whether the latter risk is due to environmental or genetic factors is unknown.

The impact of obesity on kidney health is of great consequence. In 2015 CKD was the second leading cause of high BMI-associated disability-adjusted life years (5.5 million) after cardiovascular disease [60]. That same year CKD also accounted for about 188,000 high BMI-related deaths.

### The obesity paradox

In contrast to its adverse association with kidney function, BMI has been shown in numerous observational studies to have a protective association with survival (Fig. 40.1). This association is known as the obesity paradox and is especially notable in patients on hemodialysis, though a similar relationship has also been seen in other chronic disease populations [61–63].

There are several possible explanations for the obesity paradox. These include increased cardiovascular stability, greater resistance against infections, and better overall fitness and less hypotension seen in patients with higher versus lower BMI [63]. Because BMI does not distinguish between different body compartments

FIGURE 40.1 Reverse association of body mass index and survival in patients with advanced chronic kidney disease as compared to the general population. Source: Reprinted with permission from [63].

or type of fat distribution, studies have tried to tease out their relationship to outcomes. In general, they report that increased fat (when it does not reflect central obesity) and especially increased muscle mass are associated with higher survival [12,64–66].

However, the obesity paradox of CKD has been criticized for its methodological limitations [67]. Detractors have raised concerns about multiple residual confounders and biases while supporters point to the general consistency of the observational data throughout numerous studies [63,67]. Regardless of the ultimate validity of the obesity paradox theory, it does not directly inform the clinically pertinent question of whether patients with CKD and obesity would benefit from weight reduction therapy. One observational study found a relationship between greater weight loss after initiating hemodialysis and higher mortality but the weight lost may have been unintentional, thus representing underlying pathology [68]. On the other hand, a recent study observed that *intentional* weight reduction via bariatric surgery in very obese individuals with ESRD improved survival [69]. The mortality rate in the surgery cohort at 5 years was 31% lower (0.69, 95% confidence interval 0.60–0.78) compared to a matched cohort getting usual care. This finding appears to challenge the concept underlying the obesity paradox that excess weight in patients with CKD is beneficial for outcomes.

### Obesity-related kidney disease

Apart from its role in promoting intermediate disease states like diabetes and hypertension, the two most common causes of ESRD [70], obesity directly damages the kidneys through putative mechanisms such as intra-glomerular hypertension, podocyte depletion, reduced

nephron endowment, upregulation of the sympathetic system and renin–angiotensin–aldosterone axis, obstructive sleep apnea, insulin resistance, lipotoxicity, fat infiltration, and adipokines. A distinct entity called obesity-related glomerulopathy (ORG) is characterized by proteinuria, glomerulomegaly, and in certain circumstances glomerulosclerosis and progression of CKD [71]. The true incidence and prevalence of ORG is not known because of different regional biopsy patterns and the fact that the clinical manifestations of ORG may be quite subtle. Clinical differences between ORG-related and primary focal segmental glomerulosclerosis (FSGS) are shown in Table 40.3.

Obesity-related intraglomerular hypertension is a result of several factors, including increased proximal tubular sodium uptake possibly from increased sympathetic activity [72], greater circulating angiotensin II (Ang II) [73], or other mechanisms. The reduced sodium load downstream deactivates tubuloglomerular feedback [74] leading to afferent arteriolar dilation, an increased filtration fraction, and direct transmission of higher (and ultimately detrimental) systemic blood pressures to the glomerulus [75]. Compounding this is a volume expanded state induced by increased proximal tubular sodium uptake [73,75–77]. A higher GFR and higher filtration fraction increase oncotic pressure in the peritubular capillaries that in turn also promotes proximal sodium absorption [73]. Taken together, the process involves a vicious cycle that promotes

structural damage within the glomerulus. The process is shown in Fig. 40.2.

Podocytes help maintain the glomerular basement membrane filtration mechanism and have limited capacity for cell division and replacement [78]. Increased caloric intake stimulates glomerular hypertrophy likely through the mammalian target of rapamycin pathway [79,80]. This causes a maladaptive response in which podocytes attempt but are ultimately unable to sufficiently hypertrophy to maintain the filtration barrier. The result is denuded areas on the capillary loops that are a nidus for segmental glomerulosclerosis. This theory is supported by evidence showing that in humans increased glomerular volume associates with reduced podocyte density and greater foot process width that are risk factors for proteinuria [81]. Ang II, aldosterone, plasminogen activator inhibitor-1, and hyperlipidemia are all upregulated in obesity while adiponectin is downregulated. All these factors have also been hypothesized to contribute to podocyte depletion [82–86].

The reason why only certain obese individuals develop ORG may be related to nephron endowment. Individuals born with reduced nephron mass and relatively low nephron numbers, such as is the case of small-for-gestational age or preterm births, are susceptible to developing hypertension and in certain circumstances kidney disease [87]. Similarly,

**TABLE 40.3** Clinical and pathologic differences between obesity-related glomerulopathy (ORG)-related and primary focal segmental glomerulosclerosis (FSGS).

Characteristic	ORG-related FSGS	Primary FSGS
Age at presentation	Most common in middle-aged adults (mean age 37–46 years) but may be present in children and older adults	Most common in children and young adults
Clinical presentation	Slowly progressive proteinuria	Sudden onset of proteinuria with full nephrotic syndrome in most cases
Proteinuria and serum albumin	<ul style="list-style-type: none"> <li>• Subnephrotic proteinuria in 52%–90% of patients</li> <li>• Normal serum albumin levels</li> </ul>	<ul style="list-style-type: none"> <li>• Nephrotic-range proteinuria in most patients</li> <li>• Hypoalbuminemia is common</li> </ul>
Full nephrotic syndrome <sup>a</sup>	Unusual (<5% of patients) even in patients with massive proteinuria	Common
Clinical course	<ul style="list-style-type: none"> <li>• Slower progression than primary FSGS</li> <li>• Renal survival 75% at 5 years and 50% at 10 years</li> </ul>	<ul style="list-style-type: none"> <li>• Faster progression than ORG-related FSGS</li> <li>• Renal survival 50% at 5 years and 25% at 10 years</li> </ul>
Glomeruli with FSGS lesions	Fewer than in primary FSGS (mean 12% of glomeruli)	More frequent than in ORG-related FSGS (mean 39% of glomeruli)
FSGS variants	Perihilar variant more common	Note otherwise specified, tip, and collapsing variants more common
Glomerulomegaly	Defining feature of ORG (100% of cases)	Variable (10% of cases)
Foot process effacement	Usually <50% glomerular surface area	Usually >50% glomerular surface area

<sup>a</sup>Hypoalbuminemia, hyperlipidemia, and edema.

**FIGURE 40.2** Hemodynamic alterations in obesity. Primary dilatation of the afferent arteriole and variable constriction of the efferent arteriole via activation of Ang II and aldosterone contribute to increases in single-nephron plasma flow, glomerular intracapillary hydrostatic pressure, and filtration rate. The major driver of afferent arteriolar dilatation is unknown, but deactivation of tubuloglomerular feedback via increased proximal tubular salt reabsorption and decreased delivery to the macula densa likely has a role. A host of factors, including Ang II, the renal sympathetic nervous system, insulin, an increase in postglomerular oncotic pressure due to increased filtration fraction, and mechanosensors of tubular flow rates, mediate the increased tubular reabsorption of sodium. The increase in filtrate flow (single-nephron filtration rate) in turn promotes glomerular capillary wall stretch tension, glomerulomegaly, and maladaptive podocyte stress leading to obesity-related glomerulopathy and focal segmental glomerulosclerosis. *Ang II*, Angiotensin II; *AT<sub>1</sub>R*, type 1 angiotensin II receptor; *TGF-β*; *TGF-βR*, *TGF-β* receptor. the presence of obesity in persons with reduced nephron mass may lead to kidney damage [88]. One line of evidence that reduced nephron endowment or mass is the key factor determining development of ORG are histological studies showing that patients with ORG have lower glomerular and podocyte density and increased glomerular size compared with controls [81,89]. However, whether fewer glomeruli are a cause or consequence of ORG has not yet been definitively established.

The deleterious renal effects of renin–aldosterone axis upregulation such as seen in obesity [90] are well established and explain why inhibitors of this axis may be effective treatments for kidney disease in overweight patients [91,92], though not all evidence supports this strategy [93]. Experimental studies in animals and observational trials in humans find that Ang II and aldosterone play an important role in obesity-related hypertension and kidney disease [94–96]. Possible mechanisms include sympathetic nerve stimulation, insulin resistance, and hemodynamic alterations that promote renal cellular toxicity and fibrosis [96,97].

Obstructive sleep apnea, elevated-circulating leptin levels, and hyperinsulinemia have all been postulated to increase sympathetic nerve activity in obesity with resultant sodium retention [72,98]. In a dog model, kidney denervation prevented a rise in blood pressure and greatly lowered sodium retention though renal hemodynamics remain unchanged [98].

In addition to increased sympathetic activity, obstructive sleep apnea has been linked to obesity-related FSGS [99] and proteinuria [100–102] though the association is not unequivocal [103]. One report described how initiation of BiPAP ventilation preceded the disappearance of nephrotic-range proteinuria in a patient with obesity-hypoventilation syndrome and biopsy-proven FSGS [102]. A postulated mechanism involves regression of pulmonary hypertension-associated abnormalities in renal blood flow and sympathetic nerve activity.

The importance of insulin-sensitivity to proper glomerular function was highlighted using a murine model in which insulin receptors were deleted from podocytes [104]. Over time the mice developed albuminuria and glomerulosclerosis. In humans the link between insulin

resistance, a hallmark of obesity and the metabolic syndrome, and kidney disease is primarily based on associative data [105,106]. Indeed, it is difficult to tease out the specific effects of insulin resistance from other abnormalities that cluster in patients with the metabolic syndrome.

Excess lipids accumulating in mesangial cells, podocytes, and tubular cells can damage cellular structural integrity and lead to maladaptive metabolic changes that contribute to kidney disease [107]. Targeting pathways involved in lipid metabolism have been shown in animal studies to limit lipid-related injury [71].

Fat accumulation in renal sinuses has been linked to kidney disease [108,109] perhaps through direct compression of renal parenchyma resulting in increased renal interstitial pressure, sodium reabsorption, and other adverse effects. Notably, weight loss has been shown to reduce renal sinus fat in persons without CKD [110].

Fat cells are now understood to secrete a range of biologically active molecules, some of which have been investigated for possible deleterious effects on the kidney [111]. Two of the most prominent are leptin and adiponectin. Leptin was first studied for its role in appetite and metabolic regulation but is now also understood to mediate the obesity-associated increase in blood pressure [112]. In addition, cell and animal models exposed to leptin develop glomerular endothelial cell proliferation, increased TGF- $\beta$ 1 secretion, and glomerulosclerosis and collagen deposition within the glomerulus [113]. Adiponectin has insulin-sensitizing effects and its levels are inversely associated with adipose mass [114]. Mice that cannot express adiponectin manifest increased levels of albuminuria and podocyte foot process fusion while treatment with adiponectin reverses these effects [86]. In observational studies adiponectin is inversely correlated with proteinuria [86,115]. A direct effect of adiponectin on podocytes is postulated to occur at least in part through stimulation of the AMP-activated protein kinase pathway that inhibits reactive oxygen species [116]. Whether adipokines truly mediate kidney disease or are simply an epiphenomenon remains open to debate as the available evidence is primarily based on in vitro or animal models that may not reflect human physiology. In addition, the fact that some adipokines are filtered and reabsorbed in the nephron makes it challenging to differentiate their biologic effects from those related to changes in GFR.

## Management of obesity-related kidney disease

### Nonweight loss strategies

Blockade of the renin–angiotensin–aldosterone (RAAS) axis with resultant lowering of intraglomerular

pressure offers a potentially effective strategy for renoprotection. A retrospective study in 17 patients with nephrotic-range proteinuria suggested that treatment with the angiotensin-converting enzyme (ACE) inhibitor captopril had the equivalent effect of weight loss in reducing proteinuria [91]. A post hoc analysis of the Ramipril Efficacy in Nephropathy trial, which randomized 352 patients with nondiabetic nephropathy to either the ACE inhibitor ramipril or matched placebo, reported that ramipril reduced the cumulative incidence of ESKD in patients who were obese and to a lesser extent overweight but had no effect in persons with normal BMI [92]. The antiproteinuric effect of ramipril also increased with higher BMI. However, a retrospective database analysis of 219,701 obese primary care patients did not find RAAS blocker use effective in preventing a 50% reduction in eGFR, ESKD, or death, even in the tiny fraction of patients with proteinuric CKD [93]. Nevertheless, despite these mixed findings, it seems reasonable given their study design limitations to consider the use of RAAS inhibitors in obese patients with CKD, particularly when they have proteinuria.

### Weight loss strategies

A standard strategy when treating CKD is to target each risk factor individually. An alternative strategy is to target them collectively by addressing the root cause—namely, obesity—through a weight reduction intervention. A large portion of obese patients across the spectrum of CKD are not only interested in losing weight but attempt to do so [117,118]. This is noteworthy because intentional weight reduction if obtainable would appear to be the most direct and intuitive strategy to help combat the adverse kidney effects of obesity. Weight reduction treatment options include anorectic medications, lifestyle and dietary interventions, and bariatric (a.k.a. metabolic surgery).

## Medications

The use of the five medications currently approved by the Food and Drug Administration (FDA) for weight loss is limited by dosing and other toxicities in persons with CKD, especially in advanced stages (see Table 40.4).

Nevertheless, early evidence for two of the five approved drugs is suggestive of renoprotective benefits. In a secondary analysis of 9340 obese patients with type 2 diabetes and high cardiovascular risk, the glucagon-like peptide 1 (GLP-1) analog liraglutide reduced the composite renal outcome by 22% over

TABLE 40.4 Long-term pharmacologic treatment for weight loss approved in the United States.

Drug (brand name)	Mechanism of action	Common adverse effects	Kidney-related precautions	Dosing adjustments	
				Stages 3–5 CKD	ESKD
Orlistat (Xenical, Alli)	Lipase inhibitor thus inhibiting absorption	Fecal incontinence, oily spotting, fat-soluble vitamin deficiency	Reports of acute kidney injury possibly from oxalate nephropathy	None	None
Lorcaserin (Belviq)	Serotonin agonist, anorexic	Headache, dizziness, fatigue, dry mouth, cough	Excreted primarily via the urine	Stage 3: Use with caution Stages 4–5: not recommended	Avoid use
Phentermine/Topiramate (Qsymia)	Sympathomimetic, anorexic	Dry mouth, constipation, paresthesia, proximal (type 2) renal tubular acidosis, calcium kidney stones	Excreted primarily via the urine	Stage 3: lower maximum dose Stages 4–5: avoid use	Avoid use
Bupropion–naltrexone (Contrave)	Inhibits norepinephrine/dopamine uptake, opioid antagonist	Nausea, constipation, dry mouth, dizziness, transient increase in blood pressure, contraindicated in uncontrolled hypertension	Excreted primarily via the urine	Low maximum dose	Avoid use
Liraglutide (Saxenda)	Glucagon-like peptide-1 agonist	Nausea/vomiting, diarrhea, anorexia	None	None (limited data—use with caution)	None (limited data—use with caution)

4 years compared to placebo [119]. In a similar exploratory study of 9901 participants, the GLP-1 receptor agonist dulaglutide improved the composite renal end-point by 15% [120]. A third trial in 12,000 overweight or obese patients with high cardiovascular risk reported that compared to placebo the serotonin agonist lorcaserin lowered the primary renal outcome by 13% over 3.5 years [121]. Both drugs achieved about a relatively modest 3- to 4-kg weight loss differential compared to placebo over the study period. While promising, caution is advised when interpreting these results as they were based on prespecified secondary outcomes so are only hypothesis-generating. Additionally, they included relatively few individuals with established CKD and harder outcomes (e.g., doubling of serum creatinine, ESKD, kidney transplant, death) were few in number and not different between the two arms. In fact, the positive results reported were due mostly to albuminuria-lowering effects.

In addition to FDA-approved medications, there are additional anorectic drugs with possible renoprotective effects. Chief among these is the new medication class of sodium–glucose cotransporter 2 (SGLT2) inhibitors, a promising new class of diabetes medications that induce about a 2- to 3-kg weight loss, and prespecified secondary analyses have reported major reductions in kidney risk [122,123]. However, the Effects of Canagliflozin on Renal and Cardiovascular Outcomes in Participants with Diabetic Nephropathy

trial, which randomized 4401 patients with type 2 diabetes and albuminuric CKD to the SGLT2 inhibitor canagliflozin or placebo, found only an 0.8-kg average lower weight in the active arm after a median follow-up of 2.6 years [123].

### Medical and lifestyle interventions

Dietary restriction, lifestyle interventions, and a combination of these in conjunction with anorectic medications have also been prospectively studied in patients with or at risk for CKD [124–128] though what is currently lacking are randomized studies that directly measure the trajectory of GFR and endpoints like ESKD, transplant, hospitalization, or mortality. Of all the available studies, one stands out for its study design, statistical power, and length of follow-up [125]. The Action for Health in Diabetes (Look AHEAD) trial randomized 5145 individuals who were overweight or obese with type 2 diabetes to an intensive lifestyle intervention or standard support and monitored weight loss over time. The intensive lifestyle intervention involved reduced caloric intake (goal 1200–1800 kcal/d) and increased physical activity (at least 175 minutes of moderate exercise weekly) while the standard support group focused on diet, exercise, and social support. Over a median 8-year follow-up period, the intensive lifestyle intervention

group lost 4 more kg than the standard treatment arm and also had minor improvements in blood pressure and hemoglobin A1c levels. A substudy of the trial examining kidney-related outcomes found a reduction in very-high-risk CKD in the intervention arm [hazard ratio 0.69 (0.55–0.87)] (see Fig. 40.3) as well as statistically significant improvements in reaching eGFR < 45 mL/min/1.73 m<sup>2</sup> [0.79 (0.66–0.96)] and a trend toward reduced albuminuria of >300 mg/g [0.81 (0.66–1.01)].

There was no difference in risk of requiring renal replacement though very few such events occurred. While this study offers hope that even modest weight loss through lifestyle or dietary interventions may slow the development and progression of CKD, it does have notable limitations. These include very few patients with preexisting CKD, few hard outcomes

achieved, and its design as a secondary analysis, thus necessitating confirmation in future studies.

### Surgical weight loss

Bariatric (also known as metabolic) surgery involves an alternative approach to weight loss that is more effective and sustained overall than dietary or lifestyle interventions. It also is superior in improving major risk factors for CKD and the metabolic syndrome such as excess adiposity, diabetes, insulin resistance and hyperinsulinemia, hypertension, and intraglomerular hypertension. In one recent randomized controlled trial, two different modalities of bariatric surgery induced a larger, faster, and more sustained reduction in the BMI, hemoglobin A1c, and fasting plasma glucose after 5 years of

**FIGURE 40.3** Cumulative incidence of very-high-risk chronic kidney disease. Too few observations were available beyond year 10 for reliable estimates. Number at risk						
Diabetes support and education	2408	2325	2203	2092	1914	854
Intensive lifestyle intervention	2423	2371	2275	2180	1987	889

follow-up compared to intensive medical therapy [129]. Specifically, 23% and 29% of patients in the two bariatric surgery arms, respectively, achieved a hemoglobin A1c of  $\leq 6\%$  versus only 5% in the medical therapy arm.

In a separate randomized trial designed specifically to measure the effect of bariatric surgery on blood pressure control, Roux-en-Y gastric bypass (RYGB) dramatically lowered the need for antihypertensive medications and/or induced remission of hypertension by 12 months compared to medical therapy [130]. In nonrandomized studies, bariatric surgery is associated with improvements with additional risk factors for CKD, including glomerular hyperfiltration [23], albuminuria [131], pulmonary hypertension, right ventricular size and function [132], obstructive sleep apnea [133], and left ventricular hypertrophy [134].

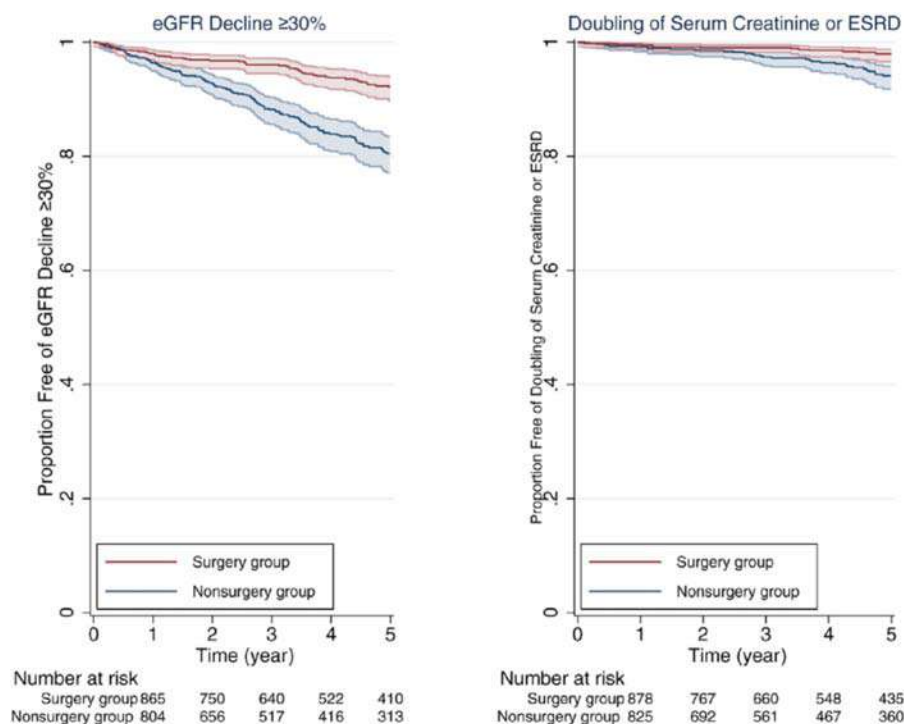

The first study to analyze the effect of bariatric surgery on kidney disease was performed by Chang et al. who compared a cohort of 985 adults with normal mean baseline kidney function with 985 propensity-matched controls. Bariatric surgery was associated with a 58% [hazard ratio 0.42 (0.32, 0.55)] lower risk of decline in eGFR and a 57% lower risk of doubling in serum creatinine or ESKD [0.43 (0.26, 0.71)] (Fig. 40.4) [135]. However, the number of events was few and the majority of persons defined as having ESKD were actually not on dialysis. A more recent study also reported a reduction in the incidence of ESKD, but similar to the Chang et al. study, the outcome definition was

liberalized to include patients not yet on dialysis and the actual events were few in number [136].

Additional reports have found benefits of bariatric surgery in a population with baseline CKD and using prognostic risk for CKD as the major outcome [137,138]. Several studies have also examined this issue in patients with type 2 diabetes, a group that may especially benefit from the effects of bariatric surgery, and found evidence albeit observational of renoprotective effects [139–142].

### Relationship between weight loss and renoprotection

Whether a direct relationship exists between the amount of weight lost and renoprotection is under debate. In a Zucker diabetic fatty rat model, RYGB was compared to equivalent weight loss by diet restriction to evaluate the effects on the kidney [143]. As compared to the ad libitum sham group both gastric bypass and diet restriction–related weight reduction approaches reduced to a similar extent the likelihood of glomerulomegaly and glomerulosclerosis, macrophage infiltration within the kidney, and urinary and parenchymal inflammatory markers. However, RYGB proved more effective in reducing proteinuria, suggesting a component of weight loss–independent benefits. This conclusion was echoed in a recent metaanalysis [144].

**FIGURE 40.4** Kaplan–Meier curves estimating time to kidney outcomes by surgery group and control group. The eGFR decline  $\geq 30\%$  outcome was defined as having a follow-up outpatient eGFR  $\geq 30\%$  lower than the baseline eGFR value. ESRD was defined as eGFR  $< 15$  mL/min/1.73 m<sup>2</sup> or treated ESRD per US Renal Data System registry. Shaded areas represent 95% confidence interval bounds. eGFR, Estimated glomerular filtration rate; ESRD, end-stage renal disease. Source: Reprinted with permission from [135].

## Management of the metabolic syndrome

Treatment of the metabolic syndrome can be directed toward each individual component or the sum total. Lifestyle modification focusing on weight reduction and increased physical activity is first-line therapy for the metabolic syndrome [145]. Antidiabetic drugs such as metformin, GLP-1 agonists, dipeptidyl peptidase IV inhibitors, and SGLT2 inhibitors, statins for dyslipidemia, and RAAS blockers for hypertension can also be considered in conjunction with lifestyle changes [146].

## Knowledge gaps

As described, there is growing evidence from a variety of studies to support the premise that intentional weight loss strategies lower albuminuria and improve or stabilize eGFR. Yet this literature has notable limitations in study design, participant selection, statistical power, and measurement issues that must be overcome to better define any kidney-related benefits. Of particular concern are the lack of data from randomized controlled trials and other studies that are large enough and/or include sufficient high-risk patients to offer sufficient power to measure effects on hard clinical endpoints like ESKD. Another limitation is the nearly ubiquitous use of eGFR rather than directly measured GFR for reasons that have previously been reviewed. A further concern is the lack of head-to-head studies comparing the risks and benefits of metabolic surgery versus nonsurgical weight reduction techniques.

## Bariatric surgery and kidney disease

Nancy Puzziferri<sup>1</sup>, Allon N. Friedman<sup>2</sup> and Bruce M. Wolfe<sup>1</sup>

<sup>1</sup>Department of Surgery, Oregon Health and Science University, Portland, OR, United States <sup>2</sup>Division of Nephrology, Indiana University School of Medicine, Indianapolis, IN, United States

### Magnitude of the obesity problem

*Prevalence of obesity:* BMI continues to be the traditional metric by which the presence and severity of obesity are expressed. The specific calculation is weight in kilograms over height in meters squared. The definitions are detailed in [Table 40.1](#).

Global figures for the prevalence of obesity in various patient populations utilized BMI > 30. In the United States, various databases put the incidence of obesity in adults at 30%–40% with some variation according to patient populations defined by race, gender, ethnicity, and others. The incidence of obesity among adolescents is 15%–17%, with the majority remaining obese as adults. While the prevalence of obesity remains exceedingly high, recent data indicate that the incidence is not increasing in the United States. While data are difficult to acquire in many parts of the world, obesity has been identified as a global epidemic.

*Clinical manifestations:* While many consider the definition in the classification of obesity by BMI to be somewhat arbitrary, the mortality risk associated with increasingly severe obesity provides the basis for declaring a BMI of >30 to represent a mortality risk with increasing mortality as BMI increases [1]. The mortality risk per BMI unit is greater in men than women with a sharp increase at BMI > 40 [1].

There are multiple comorbidities associated with increasingly severe obesity. The occurrence of multiple comorbidities complicates the estimation of the determination of the risk of obesity apart from these comorbid conditions, including risk factors for chronic kidney disease (CKD) and cardiovascular disease as outlined later.

*Glucose metabolism:* The prevalence of insulin resistance among people with obesity is 63% (BMI 30–34.9) [2] and may be greater for BMI > 35. Factors involved

include interference with the action of insulin on glucose uptake in muscle by inflammation and free fatty acids among others. In addition to diminished glucose uptake, insulin resistance occurs secondary to failure of hyperglycemia and/or hyperinsulinemia to suppress hepatic gluconeogenesis. Prediabetes may commonly progress to diabetes. Details of the adverse clinical manifestations of diabetes are beyond the scope of this chapter. Diabetes is a well-known cause of CKD.

*Cardiovascular disease:* There are multiple manifestations or comorbidities of obesity that contribute to the risk of cardiovascular disease. These include but are not limited to diabetes, hypertension, dyslipidemia, and obstructive sleep apnea. In addition to atherosclerotic occlusive disease, cardiomyopathy with secondary congestive heart failure and venous thromboembolism are direct comorbidities of obesity.

*Cancer:* The association of multiple cancers with obesity has been identified. The relative risk (RR) of certain cancers compared to normal weight individuals includes endometrium (RR 6.3), breast (RR 2.1), gastrointestinal (GI) cancers from esophagus to rectum (RR 1.8–2.6), kidney (RR 1.7), and others. Virtually all malignant diseases, including melanoma, are associated with increased risk in people with obesity other than lung cancer, which is dominated by smoking. The incidence of the association of cancers in men is elevated, although not as much as in women. In addition to the previous cancers, cancer of the liver is increased in men (RR 4.5) [3].

*Quality of life/psychological impairment:* Obesity causes decreased physical functioning due to musculoskeletal disease as well as weight itself. Impaired quality of life, depression, and suicidal ideation may also develop [4,5]. Social impairment such as limited employment opportunities and other social manifestations of obesity-related bias are also highly prevalent.

There are multiple other comorbid conditions too numerous to include in this discussion.

The incidence of these comorbidities steadily or progressively increases with the severity of obesity [6]. For example, the prevalence of each comorbidity with the possible exception of hypertension is progressively greater as the BMI rises above 40, 50, and 60 [6]. Pertinent to these data is the very high prevalence of comorbidities associated with a risk of subsequent endpoints such as cardiovascular disease and CKD. These endpoints have often not been identified among the bariatric surgery population. As a result, there is an opportunity in many of these patients to improve such outcomes through weight loss [7].

### Pathogenesis of obesity

The major components of the pathogenesis of obesity are excessive energy intake and sedentary lifestyle/diminished physical activity and energy expenditure. Of these, excess energy intake is the predominant factor. While precise data are difficult to acquire, it is evident that the excessive intake is largely due to the production and promotion of high-energy foods that are appealing to a wide majority of people at low cost. For example, in the United States, the percentage of income necessary to consume excess energy is lower than for any population in history [8]. There are numerous factors that contribute to the severity of obesity in addition to the readily available food produced and marketed to meet desirable taste. Genetics is one such factor. There are definite congenital causes of obesity which lead to severe obesity among young children, although these syndromes, such as the Prader–Willi syndrome, are rare. The role of the genetics in the present obesity epidemic is much more difficult to identify with precision due to the multiple genes which may contribute to obesity and the interaction of combinations of these genes with one another as well as the environment. Observed phenomena, precise mechanisms of which have not been identified, include variable sites at which triglyceride is stored. Uptake and storage of excess energy as triglyceride by subcutaneous adipocytes is associated with lesser degrees of secondary pathology than is accumulation of lipid at pathologic sites such as liver and muscle. While the accumulation of triglyceride in hepatocytes is reversible with weight loss for the most part, steatohepatitis, leading to fibrosis, cirrhosis of the liver, and ultimate liver failure as well as hepatocellular carcinoma, is one example of the clinical manifestations of a variation in the site of accumulation of fat and related pathology. As with many conditions, the induction of variable systemic inflammation is thought to be a primary

mechanism by which these comorbid conditions may occur. The mass of the accumulated fat may also be a pathogenic factor in conditions such as obstructive sleep apnea, musculoskeletal dysfunction, and disability.

### Role of bariatric surgery

Two distinguishing features of weight loss after bariatric surgery are the magnitude of weight lost and its long-term maintenance [7,9,10]. Obesity is a chronic disease, and while weight may be lost with medical or lifestyle interventions, weight regain ensues in over 95% of patients, even with continued participation treatment [11]. Despite the efficacy of bariatric surgery <1% of patients for whom it is indicated actually access it. Indications for bariatric surgery last discussed in published consensus guidelines [12] agreed with previous 1991 NIH guidelines [13]. Bariatric surgery is indicated for patients with BMI >40 or 35–39.9 kg/m<sup>2</sup> with high-risk comorbidities for whom medical and/or lifestyle interventions have failed to achieve or maintain adequate weight loss to improve their health. High medical-risk comorbidities include those that increase risk for cardiovascular disease and include the two most common causes of end-stage kidney disease (ESKD)—type 2 diabetes and hypertension. Other high-risk comorbidities are hyperlipidemia, sleep apnea, insulin resistance, coronary artery disease, and disabling joint disease.

Relative and absolute contraindications to bariatric surgery are preexisting illnesses which increase perioperative risk to unacceptable levels. Examples are severe-stage liver cirrhosis, undiagnosed/untreated sleep apnea, or cardiac disease, American Society of Anesthesiologists physical classification >4, and inability to tolerate general anesthesia. A patient should not be pregnant or have untreated, active cancer. Preexisting conditions that may increase the perioperative risk of surgery but do not necessarily preclude undergoing bariatric surgery are the history of venous thrombosis/pulmonary embolism, dependence on glucocorticosteroids, autoimmune disease, or previous abdominal operations. ESKD alone is not a contraindication to bariatric surgery. Most bariatric surgery programs will withhold operating if patients are current smokers, drug/alcohol abusers, or have untreated Axis I diagnoses (psychiatric diagnoses other than mental retardation or personality disorders). Appropriate cessation of unhealthy or controlled substances, or treatment to control psychiatric symptoms in these patients can reestablish suitability to undergo bariatric surgery.

## Bariatric operations

The most frequently performed bariatric operations in the United States are, in decreasing order, vertical sleeve gastrectomy (58.1%), Roux-en-Y gastric bypass (gastric bypass; 18.7%), gastric band (3.4%), and biliopancreatic diversion/duodenal switch (BPD/DS; 0.6%) [14]. Worldwide frequencies share a similar volume ranking [15]. The vast majority of bariatric operations are done laparoscopically [16]. Each operation employs a method for decreasing the stomach's capacity to take in a large volume of food (Fig. 41.1). Sleeve gastrectomy, gastric bypass, and BPD/DS accomplish decreasing the stomach reservoir capacity by resection or division. The gastric band decreases stomach reservoir capacity by partitioning a small area of the proximal stomach, and by doing so, it delays delivery of food to the distal stomach. While the

mechanisms of weight loss for these operations vary, caloric restriction is common to all, in part, accomplished by reducing the stomach's ability to accommodate a large volume of solid food. Physical symptoms ranging from discomfort or nausea to pain or vomiting often develop if excess volume of food is consumed. Thus learned behavior or a conditioned response to avoiding uncomfortable physical symptoms after "overeating" contributes to patients voluntarily limiting their dietary intake.

Sleeve gastrectomy, gastric bypass, and BPD/DS benefit from the hormonal changes of decreased ghrelin and increased GLP-1, at least within the first post-operative 6–12 months [17,18]. Decreased ghrelin reduces hunger and higher GLP-1 increases satiety. These hormonal changes stem from an early delivery of food to the proximal intestine. Food reaches the intestine quickly, relative to native anatomy, as either

**FIGURE 41.1** Anatomy of bariatric operations. (A) Sleeve gastrectomy—the stomach is reduced by vertical resection of the greater curvature creating a narrow tube or “sleeve.” (B) Roux-en-Y gastric bypass—the stomach is divided creating a proximal “pouch” of 15–30 mL. The pouch is connected to a 90- to 150-cm alimentary limb, in turn, connected to a 45- to 60-cm biliopancreatic limb. (C) Adjustable gastric band—a band with a balloon on its internal diameter circles the proximal stomach and is imbricated, creating a “pouch” of 20–30 mL. The balloon, connected to a peripheral injection port, may be tightened by saline infusion or deflated. (D) Biliopancreatic diversion—a proximal 200- to 500-mL “pouch” is created after a partial distal gastrectomy. Varying lengths of alimentary and biliopancreatic limbs are connected to create a 50- to 100-cm common channel. (E) Biliopancreatic diversion with duodenal switch—a sleeve gastrectomy replaces the partial distal gastrectomy, the pylorus is preserved and the proximal duodenum connected to the alimentary limb. Varying lengths of alimentary and biliopancreatic limbs are connected to create a 50- to 100-cm common channel.

the altered stomach empties faster (sleeve gastrectomy, BPD/DS) or as a result of intestinal rerouting and bypassing the duodenum (gastric bypass, BPD/DS). The gastric band does not benefit from hormonal changes supporting early satiety or decreased hunger [19] and results in less weight loss.

A third mechanism of weight loss after bariatric surgery was traditionally thought to be malabsorption. Malabsorption does not occur with sleeve gastrectomy or gastric band as anatomy distal to the stomach/full intestinal nutrient absorption is unchanged. In gastric bypass and BPD/DS, the proximal intestine is bypassed (approximately 45–60 cm after gastric bypass; varying greater length after BPD/DS), and there is potential for the malabsorption of micronutrients. Contrary to previous teaching, macronutrient malabsorption after gastric bypass is limited [20,21] so contributes only minimally to weight loss. BPD/DS can lead to significant macronutrient malabsorption enhancing weight loss versus other bariatric operations [20,22]. After 2 years post-BPD/DS patients are able to maintain weight loss despite eating approximately 2850 kcal/day [23].

### Outcomes of bariatric surgery

Bariatric surgery versus usual-care controls with obesity results in significant, sustained weight loss and

improvement or remission of obesity-related comorbidities [9,10,24]. In addition to improving CKD and type 2 diabetes, as noted in Chapter 40, Nutritional and Metabolic Management of Obesity and the Metabolic Syndrome in Patients With Chronic Kidney Disease, hypertension, hyperlipidemia, and sleep apnea also improve or go into remission [7,25–29]. Mortality from and incidence of myocardial infarction, stroke, and cancer are lowered compared to nonsurgical controls [30,31]. Health-related quality of life, 5–25 years after bariatric surgery, also shows significant improvement of physical scores by repeated self-report measure [32]. Mental health outcomes in these same studies have, however, been inconsistent.

Comorbidity resolution after bariatric surgery results from weight loss and may vary in the amount required for the improvement of individual comorbidities. Either a direct relationship between comorbidity improvement and weight loss exists (type 2 diabetes) [33] or a threshold weight-loss effect is required (sleep apnea) [27]. It is important to note that, similar to other medical treatments, there is a variation in weight-loss response to certain bariatric operations. The variation in weight loss is greater for sleeve gastrectomy and gastric band versus gastric bypass (Fig. 41.2) [7,26]. Despite less weight loss in lower treatment responders, weight-loss maintenance is still robust 5–7 years after surgery.

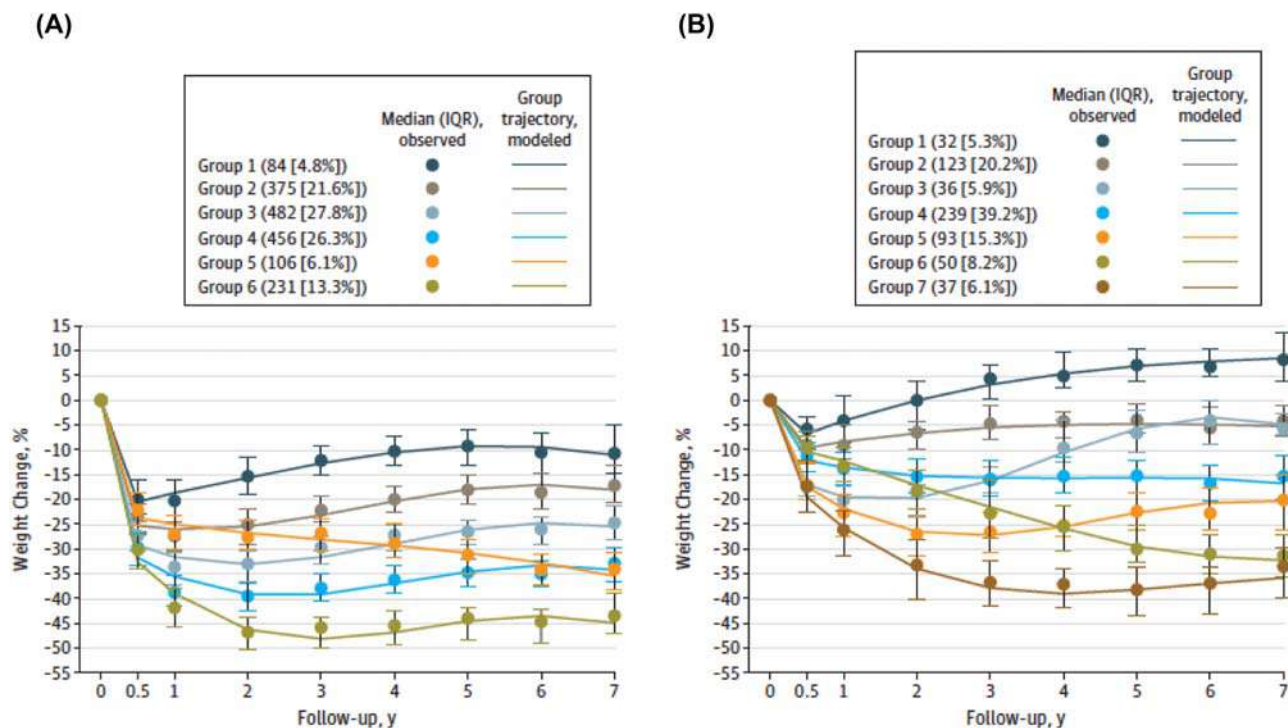

FIGURE 41.2 Percentage of weight change trajectory groups following bariatric surgery: (A) Roux-en-Y gastric bypass and (B) laparoscopic adjustable gastric band. Lines indicate modeled group trajectories, data markers, and median values; bars, IQR of observed data. Negative value indicates weight loss. IQR, Interquartile range.

## Complications of bariatric surgery

While bariatric surgery is considered a safe elective operation, it is not without complications. Most bariatric programs are accredited by the American College of Surgeons and subscribe to reporting of outcomes to a national database for quality outcome assurance. Morbidity and mortality are classified as early—within 30 days of operation, or late—> 30 days after operation. Mortality, both early and up to 1 year, is low, <0.5% for all laparoscopic bariatric operations. Complication rates within 30 days are those common to all abdominal operations: bleeding (2%), venous thromboembolism (<0.5%), wound infection (1%–2%), obstruction (<1%), reoperation (<6%), and anastomotic leak (<1%) [34–36]. Though more common early (<20%) [36], nausea, vomiting, and dehydration may also occur late leading to malnutrition if chronic. Dumping, usually seen only after gastric bypass, occurs infrequently (<5%) and often resolves over time or with dietary limiting of simple carbohydrates. Perioperative complications vary by particular operation with gastric band being the least, followed by sleeve gastrectomy, gastric bypass, and BPD/DS. Complications usually seen within 30 days may also occur late, though when occurring late, do so with diminished frequency.

Late complications include reoperations for internal hernia, gastroesophageal reflux disease refractory to medical care, stricture causing obstruction, hypoglycemia refractory to dietary manipulations, malnutrition, treatment failure, and marginal, perforated or bleeding ulcer [7,25,26,37]. Few studies following patients for a minimum of 2 years report long-term complications (<3%), and fewer report them as a primary outcome [37]. Comprehensive long-term complication rates are evolving. Nutritional deficiencies and nephrolithiasis are more common after gastric bypass or BPD/DS [25,37]. Complications of postsurgical substance abuse, including alcohol (preoperative prevalence 10%, postoperative prevalence as high as 35%) [38], may occur at any time and require long-term surveillance for discovery and treatment.

## Postbariatric surgery dietary management

The primary objective of bariatric surgery is to accomplish weight loss. Most of the secondary manifestations, including comorbidities, improve or resolve as a result of weight loss. The traditional construct of bariatric surgical procedures, as well as medical weight loss interventions, is that the weight loss is achieved by a reduction in nutrient intake and increased physical activity. Detailed studies of physical activity following bariatric surgery, however, have not

demonstrated increased physical activity in this population on average [39]. Thus decreased intake is the predominant mechanism by which weight loss is achieved [21].

Malabsorption has long been presumed to be an important component of the negative energy balance and weight loss following gastric bypass, BPD/DS, and possibly sleeve gastrectomy. For example, adding a degree of intended malabsorption is the intent of the distal gastric bypass in which a more distal connection of the jejunum (150 cm) is performed. Detailed study of the contribution of malabsorption of this operative procedure to the reduction in net energy absorption utilizing sophisticated isotopic methodology showed that the malabsorption of combustible energy represented approximately 6% of the total reduction at 5 months and 11% of the total at 14 months [21]. It is, therefore, clear that careful attention to nutrient intake is of primary importance following bariatric surgical procedures. By 4 weeks postoperative the patients are generally ready to move toward a solid food diet from the early postoperative liquid diet. The general recommendations regarding nutrient management following bariatric surgery are detailed by Mechanick et al. as the guidelines established by the American Association for Clinical Endocrinologists, the Obesity Society, and the American Society for Metabolic and Bariatric Surgery [40].

**Carbohydrates:** Carbohydrate intake is reduced secondary to the mechanism described earlier as well as in some patients learning behavior change due to symptoms of “gastric dumping.” A component of this sensation is the rapid entry of free glucose/sugars into the jejunum where rapid absorption occurs leading to very rapid rise in plasma glucose followed by a rapid fall secondary to exaggerated insulin secretion. Despite these phenomena, carbohydrate intake generally represents approximately 50% of energy intake. Variable energy intake presumably accounts for the great majority of the wide variation in weight loss which follows bariatric surgery [7]. Approximate median or mean weight loss by the first year after bariatric surgery is gastric bypass, 27%–33% [29,41–43]; gastric band, 12%–18% [41,43]; sleeve gastrectomy, 27% [29]; and BPD/DS, 45% [42].

**Fat:** Fat consumption is regularly reduced similar to the reduction in carbohydrate intake leading to enhanced weight loss. Fat malabsorption contributes little to the negative energy balance. Micronutrient malabsorption as well as increased absorption of oxalate may be associated with malabsorption of lipids.

**Protein:** Diminished protein intake occurs largely as the result of a total reduction in nutrient intake in early months following bariatric surgery. Rapid weight loss, including the weight loss following bariatric surgery, results in the loss of lean body mass (predominantly

muscle) of 10%–20% [71] [45]. This loss of lean body mass can be minimized with increased protein intake up to as much as 2.5 g protein/kg/d [46], but consumption of this amount of protein is not feasible following bariatric surgery. In addition, it is not possible to consume high-protein foods sufficiently to provide such high-protein intake without creating excess energy intake and thereby minimizing weight loss. Thus recommendations for protein intake are in the range of 0.8–1.2 g protein/kg/d [40]. Protein supplementation with high-quality protein is commonly recommended. Despite the supplementation the loss of lean body mass is approximately 10%–20% as noted earlier. Protein intake of 60–80 g/d is generally recommended. The supplementation of protein intake with essential amino acids has been shown to stimulate muscle protein synthesis in clinical trials, although none has involved bariatric surgical patients [47,48]. Manifestations of insufficient protein intake commonly seen include alopecia, anemia, and possibly low serum albumin.

**Micronutrients:** Micronutrient deficiency may occur due to both diminished intake and malabsorption. Malabsorption of micronutrients may occur and be clinically significant despite the minimal malabsorption of macronutrients. It should be noted that any procedure designed to increase malabsorption to enhance weight loss may or may not accomplish this goal but is regularly associated with the malabsorption of micronutrients which can be problematic.

**Calcium and phosphorus:** Diminished bone mineralization has been demonstrated by imaging [49]. Markers of metabolic bone disease have also been demonstrated to be increased. A degree of malabsorption of calcium, vitamin D, and phosphorus may occur. Thus increased supplementation is routinely recommended, including vitamin D in higher doses than recommended for general prophylaxis. Doses as much as 50,000 unit/d of vitamin D2 or D3 may be required [40].

**Iron:** Iron-deficiency anemia may occur in the absence of evidence of blood loss due to diminished intake and malabsorption. Thus supplementation is routinely recommended and intermittent IV iron supplementation may be required in addition to oral.

**Vitamin B12:** Deficiency of vitamin B12 due to the 90 + % exclusion of the stomach may occur. Oral supplementation of crystalline vitamin B12 at a dosage of 1000 µg daily is generally sufficient to maintain a vitamin B12 status. Parenteral B12 supplementation can be done intermittently as needed.

**Thiamine:** Thiamine supplementation should be included in the routine multivitamin and mineral supplementation. Thiamine deficiency may be exaggerated by protracted vomiting and/or alcohol intake. Manifestations of thiamine intake can be devastating due to central as well as peripheral neuropathy.

Suspected thiamine deficiency is treated with intravenous thiamine prior to the provision of glucose-containing intravenous fluids.

**Copper:** Copper supplementation is also included in the routine multivitamin/mineral preparation. Copper deficiency is manifested as anemia, neutropenia, and possible myeloneuropathy. If identified, intermittent IV copper supplementation may be required in addition to oral copper.

**Nutrition management of postbariatric surgery patients with CKD:** The extent or stage of CKD is a primary determinant of the nutritional recommendations in patients with CKD. The National Kidney Foundation clinical practice guideline for nutrition in CKD “2020 update” has recently been published by the Kidney Disease Outcomes Quality Initiative/Academy of Nutrition and Dietetics (<http://www.kdoqi.org>). These guidelines must be considered in conjunction with the postbariatric surgery guidelines as specific nutrient considerations occur in both clinical situations and may differ somewhat.

**Protein intake:** As noted earlier, deficient protein intake is relatively common following bariatric surgical procedures leading to a substantial decrease of lean body/muscle mass, alopecia, anemia, and low serum albumin. Thus protein intake higher than 0.8 g/kg/d may be recommended, although actual protein intake is generally substantially less than recommended. This leads to a recommendation of 60–80 g protein/d. The recommended protein intake in the presence of CKD is 0.55–0.60 g/kg/d (<http://www.kdoqi.org>). Further reductions of protein intake may be recommended in CKD patients. The addition of ketoacids or essential amino acid supplementation may also be beneficial [47,50]. Thus in bariatric surgical patients with early-stage CKD, sufficient protein intake to accomplish the repletion of protein depletion is appropriate with the restriction of protein intake only in the later stages of CKD. Supplementation with vitamins and minerals is generally recommended for patients with CKD unless a specific evidence of excess/increase or toxic levels is demonstrated.

**Folic acid and vitamin B12:** Beyond the standard recommendation for bariatric surgery patients, additional supplementation of folic acid and vitamin B12 is indicated in patients who have demonstrated deficiency of these nutrients.

**Vitamin C:** Vitamin C supplementation is recommended as in bariatric surgical patients without CKD and is routinely included in vitamin/mineral supplementation.

**Vitamin D2/D3 and calcium:** Insufficiency/deficiency of vitamin D is more prevalent in patients with CKD stages 3–5 than in the general population. It is, thus, reasonable to presume that additional supplementation of vitamin D2/D3 and calcium is necessary in bariatric

surgical patients with CKD. Serum levels should be monitored to guide dosage to ensure adequate intake.

**Vitamins E and A:** Research is incomplete regarding the role of CKD in determination of the appropriate intake of vitamins E and A. Thus routine supplementation is recommended in the standard supplement doses following bariatric surgery.

**Vitamin K:** Vitamin K is a fat-soluble vitamin and, thus, may be malabsorbed in patients following malabsorption procedures. The primary manifestation is coagulopathy. Studies of vitamin K status include studies of coagulation. An increased requirement for CKD patients following bariatric surgery, however, has not been clearly demonstrated.

**Trace minerals:** There is a lack of definitive research regarding a requirement for higher doses of supplementation of selenium, zinc, or other trace minerals in bariatric surgery patients with CKD. Thus continuation of the recommended daily allowance is recommended.

**Bariatric surgery post kidney transplant:** There are no immediate specific recommendations regarding kidney transplant patients, other than careful attention to the development of nutritional deficiencies, including protein, minerals, and vitamins to guide supplementation. In general, postbariatric surgery and kidney transplantation patients should be managed as usual for bariatric surgical patients.

### Role of bariatric surgery in chronic kidney disease

Several studies have addressed the impact of bariatric surgery on kidney disease. The first such published report matched 985 adults with a mean baseline estimated glomerular filtration rate (eGFR) of 97 mL/min/1.73 m<sup>2</sup> who underwent bariatric surgery (primarily gastric bypass) with 985 propensity-matched controls [51]. Over a median follow-up of 4.4 years bariatric surgery patients had a 58% lower risk of a decline in eGFR of  $\geq 30\%$  [hazard ratio 0.42 (0.32, 0.55)] and a 57% lower risk of doubling in serum creatinine or ESKD [0.43 (0.26, 0.71)] compared to controls. In that study the definition of ESKD included patients with an eGFR  $< 15$  mL/min/1.73 m<sup>2</sup> ( $N$ , surgery = 14, controls = 40) who were not necessarily on dialysis as well as persons requiring dialysis or transplantation ( $N$ , surgery = 8, controls = 10).

Kidney outcomes were also measured in a nonpre-specified secondary analysis of the Swedish Obese Subjects study, which is an ongoing prospective observational trial in 2010 patients with mean baseline eGFR of 92 mL/min/1.73 m<sup>2</sup> who underwent bariatric surgery (vertical banded gastroplasty 68.1%, gastric band 18.7%, gastric bypass 13.2%) and 2037 matched

controls [52]. Over 22 years the cumulative incidence of ESKD, defined as a composite endpoint of eGFR  $< 15$  mL/min/1.73 m<sup>2</sup>, dialysis, or kidney transplantation was reduced by 73% in the bariatric surgery cohort compared to controls after adjustment for confounding baseline factors [0.27 (0.12, 0.60)] (Fig. 41.3). However, the incidence of ESKD was very low overall (bariatric surgery = 13; controls = 26) and the number of subjects reaching each specific endpoint was not reported.

Friedman et al. studied the impact of bariatric surgery in 2144 adults enrolled in the National Institutes of Health-sponsored multicenter, prospective Longitudinal Assessment of Bariatric Surgery-2 (LABS-2) cohort, which was designed to study the long-term safety and efficacy of bariatric surgery [53]. The primary renal outcome was CKD prognostic risk, which was measured using established criteria that combined eGFR and albuminuria, the two main clinical indicators of CKD. By year 7 of follow-up, bariatric surgery was associated with improvement in CKD risk, even in patients with higher CKD risk at baseline (proportion of patients with improvement by baseline CKD risk: moderate—53%, high—56%, very high—23%). Importantly, the study did not include a comparison group, and the median baseline eGFR was 96 mL/min/1.37 m<sup>2</sup>.

In the only published study performed exclusively in patients with CKD, Imam et al. compared propensity-matched patients who underwent gastric bypass or sleeve gastrectomy with patients who were referred for but did not have bariatric surgery. At baseline, 66% of individuals had diabetes and a mean eGFR of about 47 mL/min/1.73 m<sup>2</sup> [54]. At 3 months postsurgery the mean eGFR in the bariatric surgery cohort rose significantly (in mL/min/1.73 m<sup>2</sup> by surgery type: gastric bypass: +17; sleeve gastrectomy: +12) while remaining essentially unchanged in the control group. The statistically significant increase in eGFR in the bariatric surgery cohort persisted over the 3-year follow-up period, although the difference between groups narrowed over time.

Recent studies have also focused on the subgroup of patients with type 2 diabetes and CKD. This is an area of great importance because diabetic kidney disease is the most common cause of CKD and ESKD worldwide [55]. In light of the close relationship between obesity and the development of diabetes, it is possible that by improving the diabetic milieu bariatric surgery could halt or possibly even reverse diabetes-induced kidney damage.

O'Brien and colleagues retrospectively examined the likelihood of developing incident diabetic nephropathy, defined by at least two measurements of eGFR  $< 60$  mL/min/1.73 m<sup>2</sup> separated by 90 days with no intervening higher levels, in 4024 bariatric surgery

**FIGURE 41.3** Kaplan–Meier estimates of cumulative incidence of ESKD in the control group compared to the surgery group. Shaded areas in the graph represent 95% CIs of the cumulative incidence. The x axes are truncated at 22 years but all observations after 22 years were included in the analyses. CI, Confidence interval; HR, hazard ratio. Source: Reprinted with permission from Paddon-Jones D, Sheffield-Moore M, Katsanos CS, Zhang XJ, Wolfe RR. patients and 11,059 matched controls with severe obesity and type 2 diabetes [56]. As compared to controls, the hazard of incident diabetic nephropathy dropped in the bariatric surgery patients by as much as 81% [0.19 (0.14–0.27)] by year 2 after which it rebounded and then stabilized by year 7 [0.45 (0.29–0.71)]. While the study did not measure effects on albuminuria, a separate report described how bariatric surgery led to a 50% regression in microalbuminuria by 5 years in patients with type 2 diabetes [57].

In the Swedish Obese Subjects study, patients with type 2 diabetes showed only a trend toward a lower incidence of ESKD [0.41 (0.14–1.18)] after bariatric surgery, though this could have been due to a relatively low event rate [52]. However, patients with higher circulating insulin, worse glycemic control, and greater albuminuria—a profile that fits many individuals with diabetes/diabetic kidney disease—had among the very lowest incidence of ESKD.

The LABS-2 consortium performed a separate analysis in all 737 bariatric surgery patients with type 2 diabetes to determine if remission of type 2 diabetes up to 5 years after surgery improved markers of kidney disease and whether gut hormones and peptides modified these effects [58]. Bariatric surgery was associated with a lower risk of increased albuminuria and

stabilization in the prognostic risk for CKD but it did not influence impaired eGFR. Interestingly, the gut peptide ghrelin modified the relationship between surgery and the prognostic risk for CKD in a protective manner. In addition, the presence of kidney disease prior to surgery reduced the likelihood of diabetes remission after surgery. This is the first study in bariatric surgery patients to examine the relationship between gut hormones/peptides and kidney-related outcomes and to evaluate how preexisting CKD affects diabetes remission rates.

In a propensity-matched analysis in obese persons with type 2 diabetes and normal baseline kidney function, 2287 bariatric surgery patients were compared to 39,267 controls over a median follow-up of 3.9 years [59]. Patients undergoing surgery were found to have a lower incidence of major adverse cardiovascular events, including nephropathy [0.40 (0.31–0.52)], which was defined as two measures of eGFR < 60 mL/min/1.73 m<sup>2</sup> at least 90 days apart with no intervening higher values.

Kidney benefits have also been observed in younger cohorts. One study frequency matched 30 obese adolescents with type 2 diabetes who underwent bariatric surgery with 63 youths who received medical therapy-based weight loss, all of whom had generally

normal baseline kidney parameters [60]. Over 2 years of follow-up the number of patients with an eGFR < 90 mL/min/1.73 m<sup>2</sup> and a urinary albumin–creatinine ratio (UACR) > 30 mg/g dropped from 7 to 0 and 8 to 1, respectively, in the bariatric surgery group, while no significant changes were observed in the medical therapy group.

Data from randomized trials are limited [51]. The Surgical Treatment and Medications Potentially Eradicate Diabetes Efficiently trial was a single-center trial that randomized 150 obese patients with type 2 diabetes to intensive medical therapy alone, intensive medical therapy plus gastric bypass, or intensive medical therapy plus sleeve gastrectomy. While the primary outcome focused on glycemic control, kidney outcomes were included as a prespecified secondary endpoint. However, because persons with a serum creatinine ≥ 1.8 mg/dL were excluded from the outset, the population had normal baseline kidney function (median serum creatinine 0.7 mg/dL, median eGFR 106–110 mL/min/1.73 m<sup>2</sup>, median UACR 6–12 mg/g). At 5 years postsurgery the UACR had fallen significantly in the sleeve gastrectomy group only [absolute decrease −5.0 mg/g (−15.0, −1.0)] as compared to the medical therapy group (<0.001). Also observed in the two surgery groups only, were within-group reductions in serum creatinine and eGFR.

### Role of bariatric surgery in kidney transplant

Bariatric surgery is considered for patients with obesity who are either candidates for kidney transplant, or struggling with weight loss post-kidney transplant. In the case of candidates for kidney transplant, many programs preclude patients with a BMI of >35 or 40 kg/m<sup>2</sup> from being wait-listed based on increased perioperative complications. The evidence shows an increased risk of delayed graft function [61,62], wound infection [62], and length of hospitalization [62] in patients with obesity undergoing transplant. The risks of graft survival and mortality are less clear, with some studies showing decreased graft survival and increased mortality with increasing BMI > 30 kg/m<sup>2</sup>, while other studies fail to show this [61]. Outcomes may differ secondary to inconsistent study populations, methods, or adjustment for comorbidities. There is clear evidence, despite BMI-related complications, that survival outcomes for all BMI categories post-kidney transplant are superior versus being on dialysis [63].

Bariatric surgery as a bridge to meet lower BMI requirements pretransplant has increased nine-fold from 2006 to 2016 [64]. Gastric bypass, yielding greater weight loss versus gastric band, was the historically preferred pre-kidney transplant. Now, >85% of ESKD

patients undergo sleeve gastrectomy [64]. Sleeve gastrectomy (vs gastric bypass) may stabilize reported inconsistent absorption of immunosuppressive medications [65] required for graft survival. Nutritional challenges of iron, vitamin D, and calcium in ESKD potentially exacerbated after gastric bypass, are less problematic after sleeve gastrectomy. While sleeve gastrectomy does produce significant, rapid weight loss, there is greater variation of weight loss [26,29], and long-term studies versus gastric bypass comparing posttransplant weight-loss durability or mortality have not been done.

Post-kidney transplant patients may develop obesity severe enough to meet the indications for bariatric surgery. Compared with matched controls, patients who undergo bariatric surgery post transplant experience sustained weight loss and improved graft and patient survival [66]. Concern for infection in the context of immunosuppression, or placing a patient at nutritional risk, should their transplanted kidney fail, are important considerations. Similar to a peritoneal dialysis catheter, the gastric band is a foreign body and may require removal in the event of blood–borne or abdominal infection. Should a graft fail with return of ESKD, a bypassed duodenum after gastric bypass or BPD/DS will present iron and calcium absorption challenges. Sleeve gastrectomy, posing neither potential infectious disease nor nutritional risks, may be the safest option.

### Cost/benefit bariatric surgery

The true costs of bariatric surgery over time, both in dollars and long- and short-term harm, are not easily determined. There is an initial increased cost to undergo the operation (\$15,000–25,000), and additional required follow-up encounters for postoperative nutritional and surgical care. Uncommonly, patients may need hospitalization for surgical complication management—technical complications such as leak (<1%) [34,35], as well as routine postoperative nausea, vomiting and/or dehydration (<10%–20%) [36]. Improved safety of bariatric operations [36] and enhanced surgical recovery programs [67] contribute to decreasing need for hospitalization in the month after surgery.

There may be an overall savings in health-care dollars downstream with improved health. The literature shows evidence for cost savings in the first few years for prescription drugs and number of health-care encounters [68–70]. As health improves with weight loss after bariatric surgery, increased cost can ensue from treatments previously withheld. Elective operations, such as joint replacement or solid-organ transplant, increase secondarily as required minimum BMI thresholds are met.

Plastic surgery demand for the reduction of excess skin also increases after significant weight loss and represents an increase in out-of-pocket expense.

Long-term studies on cost effects of increased longevity because of decreased comorbidities are lacking. The cost/benefit ratio is different for different patient subgroups. The subgroup with type 2 diabetes is financially costly to a health-care system and remission and/or partial remission of diabetes occurs in 28%–90% of patients with weight loss after bariatric surgery. Remission/partial remission of diabetes brings a significant cost savings in prescription medications and the avoidance of costly long-term complications, including dialysis for kidney failure, blindness, limb amputation, cardiovascular disease, and cerebrovascular events. Interrupting the progression of kidney disease with weight loss after bariatric surgery, and eliminating the need for dialysis, bears researching to determine its quality of life and cost value.

Overall the cost-effective modeling and analyses for bariatric surgery are based primarily on gastric bypass and band outcomes. Current literature is relatively limited in our era of sleeve gastrectomy dominance. Analyses of long-term data generated by closed systems, such as health-maintenance organizations, or nationalized health-care systems, which include sleeve gastrectomy as well as gastric bypass, may provide the best answers to overall and patient-subgroup cost or savings after bariatric surgery.
